

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. OF
MEDICINE AND THE COLLATERAL SCIENCES.

VOL. V.

(SEPTEMBER 26, 1829, to MARCH 27, 1830)

LONDON:
PRINTED FOR LONGMAN, REES, ORME, BROWN, AND GREEN,
PATERNOSTER-ROW.

1830.

2 BARON HEURTELOUP'S METHOD OF PERFORMING CATHETERISM.

But if the *lithotomist* was not obliged to sound in such a way as to ascertain correctly all the particulars, it is absolutely necessary that the *lithotritter* should inform himself accurately of the state and form of the organ in which his instruments are to act, and of the stone against which the action of those instruments is to be directed.

After first discovering the stone, he must appreciate its size, density, nature, form, and position; ascertain the form and capacity of the urethra; the shape and size of the bladder—the greater or less regularity of its internal surface—the extent from the neck to the side—its depth below the neck—its width and power of contraction; for these are all circumstances the knowledge of which is essentially necessary to the lithotritter, and without which he cannot act with that certainty and precision which an operation requires, where its success depends on the strict observance of all the rules of prudence, the exact knowledge of the organ in which he is about to operate, and of the body which he is to destroy.

In the impossibility of obtaining all this with the sound generally used for this purpose, it was found necessary to give another form to the instrument, with which the exploration of the bladder might be conveniently made.

This instrument is a silver tube, two lines and a half in diameter, having a stop cock at the end, forming the handle. It is perfectly straight, and 8 inches in length to the commencement of the curve at the extremity. Its curve is exactly represented by the quarter of a circumference of a circle, the radius of which is an inch and a half. At the curved extremity there are two eyes, one at each side; and half an inch from its extreme point it screws off, that it may be cleaned with greater facility. The handle end is adapted for the reception of the pipe of the syringe, and, being lined with leather, fits sufficiently accurately to allow the injection of water to be made without any portion escaping by the side. The stop cock, which is inserted a little below the point of the syringe, by being turned, prevents the return of the fluid when enough has been injected; and with this instrument M. Heurteloup performs the sounding, which he designates the "Methodical Recto-curvi-linear Catheterism."

The Catheter, with the mouth to which the pipe of the syringe is adjusted when it is used. A little lower down is the stop-cock.

a This is to enable the pipe to be unscrewed when the syringe is cleaned.

M. Heurteloup's syringe is of silver, with the end of the piston forming a ring; there is also one at each side of

the neck. Thus the fore and middle fingers are introduced through the rings at each side, while the thumb is inserted in the ring end of the piston; so that the syringe can be held and the injection made with one hand, which has the great advantage of leaving the other at liberty to support and direct the sound*.

Such, then, are the two instruments by which the Baron sounds the bladder of a patient in which he suspects a stone, and when he is desirous of ascertaining the fitness of the case for operation. Before commencing the sounding process, he takes care to empty the rectum; because this intestine, accordingly as it is more or less filled, alters the form of the bladder, and increases or diminishes its extent where they are in contact; and as it is precisely in this part of the bladder that the instruments are extended, it is evidently of importance. The patient is sometimes subject to internal hemorrhoids, and these may be so much developed as to project considerably, and consequently form indentations in that part of the bladder.

This precaution taken, and the patient placed on the side of his bed, flat on his back, the head a little raised, and each of his legs placed on a chair, the catheterism is effected with much gentleness. When the extremity of the sound is under the pubes, the curvature of this instrument being exactly adapted to the curve of the urethra from the pubes to the neck of the bladder, it is passed in by merely slightly depressing it. By continuing to depress the sound, and advancing it a little, the whole of the curved part is in the interior of the organ, while that which is straight is entirely in the canal.

From this moment M. Heurteloup is satisfied that the canal will allow the passage of a straight sound, for by the simple act of pushing the curve of the sound into the bladder, the whole of the urethra is brought into a straight line†.

In giving to the sound thus situated

* M. Heurteloup has called this the *surgical syringe*, to distinguish it from the ordinary syringe, which requiring the use of both hands, does not leave the left free.

† As soon as the sound has thus entered the bladder, the stop cock is turned, to allow all the urine in the organ to flow out, and he injects in its place warm water, until the patient feels a moderate desire to void it. The injection, and the consideration more particularly regarding it, are too long to be entered into here. It will be seen in this paper, that the bladder changes form in proportion as there is more or less water injected. There are certain laws respecting the injection.

a slight movement forwards, he estimates, by the manner in which it is grasped, whether the introduction of the straight sound will be easy or difficult. If he can make this movement with the sound easily, it is a proof that the different parts of the canal may be brought into a straight line with facility; if, on the contrary, the sound is tightly grasped, it will be more difficult, and the operation probably more painful.

It must not be believed, therefore, that because the sound is grasped the passage is narrow, for this often happens in very large urethrae. The difficulty of passing it, which is sometimes considerable, depends upon each of the parts of the canal not being readily brought into a straight line.

When the canal is thus in a straight line, the greater or less play of the instrument depends on the degree of laxity of the parts, which give to the canal its natural curvature. When the straight part of the sound is in the full length of the urethra, the end in the bladder is carried upwards by the position of the neck, and equally upwards at the handle by the suspensatory ligament, while it is bound down below by the resistance which the pubes offers; and if the os pubis be very low, the suspensatory ligament very short, and a large prostate greatly raise the neck, these are sufficient reasons for the tight grasping of the sound; for, carried upwards at both extremities, and kept below by the pubes, it is not by the narrowness of the passage, but because it passes three points of the canal, which are brought with difficulty into a straight line, that the instrument is grasped.

When the sound is thus grasped it is an unfavourable condition, for the straight instrument will of necessity be introduced with greater difficulty, less easily suffered, and less easily manœuvred.

Hence he knows, as soon as he has moved the sound a few times forward and backward, if the crushing the stones will be easy or not, as far as the greater or less facility of the canal for the passage of straight instruments is concerned.

Besides ascertaining if the sound moves easily in the canal, he profits by these motions to find out what distance exists between the neck of the bladder and that part of its sides immediately opposite. This calculation is easily made in pushing the sound to the bot-

4 BARON HEURTELOUP'S METHOD OF PERFORMING CATHETERISM.

lom of the organ, and withdrawing it towards the neck: the play of the instrument allows the extent across to be easily ascertained, for the curvature being abrupt, the hooking it below the neck is very perceptible. This movement, therefore, enables him to decide whether the operation would be easy with regard to the extent from before backwards of the bladder. The facility of the operation will be in proportion to this extent, which varies ordinarily from two to four inches, but which is most generally from two inches and a half to three inches*.

By carrying the extremity of the sound from right to left, M. Heurteloup ascertains whether the bladder has sufficient width to allow the operation to be performed with facility. The extent in this direction the best adapted for the advantageous performance of the operation, is assuredly that which, at the same time that it gives sufficient room for the expanding of the instruments, is not so large as to allow the calculi or fragments to lodge themselves at the sides. The bladders which combine these two conditions are those in which the extent from side to side is three inches. It is desirable, then, for the surgeon to ascertain if the organ which he is

* It is this limited extent of the bladder from before backwards which renders the three-branch instrument, used for the destruction of calculi, often dangerous, the branches of which require to be extended a considerable distance beyond the tube, to seize a large stone: if these branches are too long, then it is impossible to manœuvre the instrument. It has been said that the three-branch instrument will seize large stones, and undoubtedly it can, but only by extending the branches very considerably beyond the extent of the external tube, which, it must be evident, renders the instrument inapplicable. It is true, if in drawing it against the neck of the bladder, efforts be made to seize the stone with the instrument "à trois branches," they would be successful, but he who thus operates no longer exercises an art, but a rude business. Nothing in this operation should be done by force; every movement should be skilfully performed, and consequently with gentleness. When it is recollected that these fatiguing and painful manœuvres which the surgeon is obliged to resort to, in order to seize a large stone with this instrument, only lead to the perforation of one hole, and that to make another the same steps must be taken, it will be a subject of surprise that any good surgeon should thus undertake to cure a patient afflicted with a stone of large dimensions.

These considerations induced M. Heurteloup to construct the "*Evideur* with *pince à forceps*." This instrument can be made to grasp, in the same manner as the forceps, large stones, with the branches projecting but a very short distance from the tube, and the branches being moveable separately allow the surgeon to seize the stone without injuring the organ: once grasped, it is scooped out until the sides break in; the fragments are then pulverized by the *bris coque*.

examining has this width. This information is easily acquired by means of M. Heurteloup's sound. The curvature of this instrument being the quarter of the circumference of a circle, the radius of which is one inch and a half; if it can be turned from right to left without the extremity coming in contact with the sides of the bladder, we must then feel convinced that it is three inches wide, since for an inch and a half at each side of the neck there is no resistance. It will be evident that the straightness of that part of the sound which is in the canal allowing the instrument to be turned on its axis, consequently permits the necessary movements to be given to the curved extremity. In order to ascertain the size of the bladder to its greatest possible extent, the Baron moves the instrument to the right and left several times, and at the same moment, by a movement forward, ascertains the depth of the organ from the neck to the part immediately opposite. He also ascertains, by moving the sound as far as possible to each side, if the bladder be much larger than the three inches he desires to find: if the beak of the sound does not touch the sides with facility, he concludes that the operation will probably require a longer time, for the fragments spread in the base of a larger bladder will no longer be placed so immediately under the branches of the instrument.

In these movements to the right and left and upwards he also determines whether the internal surface of the bladder presents many irregularities; as, for example, those fleshy columns which are often met with, and polypus excrescences which are sometimes found attached to the walls of the bladder, and particularly near the neck. It will be seen of how much importance it is to be aware of these excrescences, for they might get entangled with the branches of the instrument with which the operation is performed.

The extent of the bladder from the neck to the opposite side, and laterally, being ascertained, it then becomes necessary to know what is the depth from the neck to the "*basfond*." If the beak of the sound be turned downwards, this will be easily estimated; if it cannot thus be carried from right to left, the depth cannot be considerable, and it will be so much less in proportion as the sound is raised upwards to the level

of the median line. If, on the contrary, the sound turned downwards can be rotated without touching that part of the bladder which is below the neck, we are then sure there must be more than $1\frac{1}{2}$ inch depth, and this is an unfavourable circumstance, for the fragments will be seized with greater difficulty, or at least it will require the instrument to be inclined more perpendicularly downwards, which will be very painful to the patient. This depth below the neck is observed principally in spare subjects. M. Heurteloup provides against the inconvenience which it occasions by raising the pelvis considerably, which he easily effects by means of the little bed which he employs in his operations: when the pelvis is elevated, the fragment is displaced from beneath the neck, and is thrown into the base of the bladder, where it is seized with facility, and without pain to the patient.

During this manœuvre of the sound, which is to give the depth below the neck, M. Heurteloup observes in what degree the rectum projects against the bladder, for the state of this intestine, as has already been observed, influences much the greater or less facility with which the operation is performed. It is of importance, then, to know if this projection be considerable; and it is not until he is perfectly satisfied as to the exact form and dimensions of the bladder* that he directs his attention to the stone, and then the recto-curvilinear sound is greatly advantageous to the appreciation of this foreign body.

The ease with which this sound may be turned on its axis, and advanced or drawn back in the canal, is of wonderful service in acquiring the necessary information; for the facility with which the sound is moved allows the surgeon the full benefit of all the delicacy and precision of his movements.

As soon as M. Heurteloup proceeds to examine the stone, his movements become more gentle, for although, from the walls of the bladder being fixed, he allows himself to make his examination as to its dimension quickly, in order to abridge the catheterism, the mobility of the stone requires greater care; if the sound be manœuvred too quickly, the stone is moved, and does not permit the surgeon to ascertain its form, nature, &c. with precision.

* It may be conceived that this knowledge is acquired with great rapidity, for each movement of the sound gives a measure.

Whatever may be the size of the stone, it is always situated in the "bas-fond" of the bladder, when the patient is in the horizontal position. It is there, then, that he always directs his instrument. When it is found in any other part of the bladder, it is because the precaution has not been taken to inject it with warm water previous to the sounding, and that it is deranged from the place which it ordinarily occupies by the introduction of the catheter. Of course moveable calculi are alone alluded to here. If the stone be large, as it is generally placed on the median line, and that its size raises it on a level with the neck of the bladder, it is felt by the surgeon immediately the instrument is introduced, for the straight part of M. Heurteloup's sound is necessarily in contact with it.

The first thing he ascertains is the mobility of the stone, for on this depends whether it can be seized by the instruments. If he finds the stone immovable, and presenting an extended surface, he concludes that it is large, attached to the base of the bladder, and consequently not a proper case for the action of the lithotritic instruments: unless, indeed, the bladder should be very healthy, and easily dilated with a very large urethra, then the stone might be broken up with success; but these conditions are very rarely found with very bulky stones.

M. Heurteloup, however, before pronouncing this judgment, examines whether this immobility may not depend on the flat form of the stone; for, by this circumstance, a calculus, though not very large, is immovable, and seems to the sound, which merely passes over it, to present a large surface: to ascertain whether the stone is of this description, he carries the curve of the sound flat to the further edge of the stone, carrying the handle towards the thigh, to which the beak is turned: he thus encloses the stone in the curve of the sound, and getting it a little beneath the calculus, he raises it. If the stone is flat, it is raised with facility, and he feels that he could turn it over; if it is round, on the contrary, it may be raised, but it immediately falls back upon the sound*.

The contact of the sound with these

* Besides, the moment when the beak of the sound is pushed under the stone, he feels easily whether it is flat, by the slight distance the sound has moved from the upper to the lower surface,

neck of the bladder with the convexity of the sound, so as to stop its return; for, whenever the stone is above the neck, it is almost impossible to gain an accurate idea of its form and size.

If the bladder should not be deep below the neck, there will be no necessity for turning the sound as has just been described; the simple introduction of it will displace the stone, and throw it off to the right or left. M. Heurteloup still alludes here to a stone of moderate size.

In fine, if the bladder contains one, two, or three small calculi—that is to say, of from four to ten lines—they will be rarely felt in the “basfond” of the bladder by the convexity of the sound; for, as soon as this part of it is carried to the posterior side, the small stone being generally light and rolling, it is moved with too much facility, and often rolls to the sides, and still more frequently below the neck. When it is placed in the lateral parts of the bladder, it is felt with the beak of the sound turned to the right and left; but the least movement, if not made with care, changes its position, and it is no longer touched by the sound. These movements ought to be more gentle and measured, in proportion as the stone is small.

When the stone is of small diameter, and is placed below the neck, it is felt with greater facility, whether the distance between it and the bottom be great or small: if there is but little depth, it is detected with the convexity of the sound, by raising the handle, and consequently depressing the neck; and if, on the contrary, the depth is considerable, the sound is turned so as to present the beak downwards; and as it can be rotated from side to side easily, the stone is certainly found, and its size and form easily appreciated. When the calculus is small, and wedged under the neck of a bladder of only moderate depth, it is touched by the sound with greater difficulty; for the convexity does not sufficiently depress the neck to touch it, and the beak turned downwards, coming in contact with the bottom of the bladder before it gets to the median line, where the stone is generally situated, cannot turn it over. In this case it is necessary to elevate the pelvis considerably; the surgeon will then be able to feel it with the convexity of the sound, for it is carried by

this position to a more distant part of the bladder, and consequently becomes more accessible.

When the bladder contains a great number of small stones, instead of three or four, the surgeon ascertains it very easily; for, collected together in the same part of the base of the bladder, the stones, when moved, convey a sensation produced by their collision against each other.

It sometimes happens, when there is but one stone and it is very small, that it escapes the most methodical researches: it is then useful, when the symptoms leave little doubt as to the existence of a foreign body, to introduce a “pince à forceps,” which is better adapted to discover a stone when it is of this small size, and permits the surgeon to seize and crush it, which converts the sounding into an operation very advantageous to the patient. M. Heurteloup has in this manner cured some patients who had small stones, which, by their great mobility, escaped the touch of the sound but not that of the pincers, which indicated their presence, and seized them at the same moment. In these cases of small stones, the “pince à trois branches” is a most useful instrument, and it was by no means with a view to supersede its use in these cases that Baron Heurteloup undertook his labours.

Such are the data which the lithotritter ought to possess before he commences the operation, and such are the means of quickly acquiring, with mathematical exactness, a knowledge of the organ in which he is going to manœuvre his instruments, and the bodies on which he is to make them act.

When the science only possessed the “instrument à trois branches” of MM. Leroy and Civiale, to arrive at the desirable result of curing calculous patients without an incision, it was, perhaps, less useful to the surgeon to appreciate with accuracy the form and size of both bladder and stone—since this instrument was applied in all cases, against large or small bodies, round or flat, a wide or narrow bladder: the surgeon having only one instrument, had no choice to make. But now, that different mechanical means of destroying the calculi have multiplied the chances of success, and extended the limits of the lithotritic art, it will be evident how important it is to be accurately informed of the different circumstances of each case,

rotunda, are in an equally perfect state, confusion of sounds must be the consequence, as the nerves spread on the whole labyrinth are so intimately connected that all the mechanical impressions made on them at the same instant must be in unison, or in such proportions as the original conformation of the labyrinth requires from its respective parts of the tympanum.

Some deaf persons cannot hear sounds that are either too high or too low, but only those that are moderate. I conceive that the several parts of the tympanum are in different states of activity in deafness, and presuming that some of the notes of music pass both through the fenestra ovalis and rotunda in modified degrees, and these two parts may be so influenced by any morbid changes as to prevent the production of motion corresponding with the degree of impression required in each of them for unison, the one must confuse or destroy the power of the other; and, therefore, if the voice or music be so managed as either to excite an equable action in both these parts, or be so adapted to one of them as quite to overpower or make no impression on the other, distinct hearing will be the consequence; and perhaps the motion of a carriage, by stimulating all the parts at the same time, produces that equable action which is necessary for fitting the deaf ear for hearing.

In the preceding case, on the restoration of the hearing for two days, the sound from the discharge of the gun acted as a stimulus to the membrana tympani and the nerves distributed in it and the tympanum. Whether the auditory nerves themselves were affected, must admit of some doubt. I have stated in a former paper, that these are not so often implicated as has been supposed; but that deafness, and the noises which accompany it, very often depended on the state of the nerves distributed in the membrane lining the tympanum. The auditory nerves themselves have very seldom been found defective or diseased, yet they may suffer either at their connexion with the brain, as when deafness is accompanied with epilepsy; or in their distribution in the labyrinth, in the same manner the optic nerves and retina do in amaurosis. But I wish to establish that, in a great proportion of habitually deaf people, these

nerves are not affected. If such conclusions lead to no improvement in the cure of deafness, it may appear a useless waste of time to enter into any discussion on the subject; but if a knowledge of the true seat of deafness be gained, a better mode of treating it will follow. If it be proved that deafness is most commonly seated in the tympanum, it is bringing the disease not only to a part more within our knowledge and nearer to the surface, through which remedies may be more efficaciously administered, but the very circumstance of its being within our reach, of its not being primarily seated in the brain and the delicate auditory nerves, may give reasonable ground for presuming that, although the nerves of the tympanum may be implicated, the diseases which involve them may be removed, and, by sufficient care, permanent deafness prevented. I conceive that the foundation of deafness is most frequently laid in childhood, and the inflammatory action which is its origin is not attended to, because it is merely ear-ache, discharge from the ear, &c.; but when this has once begun, exposure to cold, disorders of the digestive organs, &c. renew it, and in time the functions of the affected part become permanently impaired. It is an undoubted fact that modern surgery has prevented not only numerous operations, but deformities; because more care has been taken of incipient complaints, and a rational method of treatment has been adopted for their removal. Why should not this same care extend to one of the most exquisitely formed organs in the body—one on which so much of the comfort of man depends, and the loss of which is so deeply lamented by those who have experienced it? If when inflammation has been set up in the tympanum from any cause, means were taken to counteract its tendency to change of structure, and these were persevered in until the restoration of the organ became perfect, and a repetition of its exciting cause then obviated, why should not deafness be rendered less frequent, as well as blindness, and deformity from diseased joints?

6, Tavistock-Square, Aug. 25, 1820.

and how desirable are these improvements in the ordinary mode of sounding.

The art of breaking up the stone in the bladder is, by its nature, a science which will only arrive at perfection by dividing it into details, and making each part as perfect as possible. The preliminary operation, which consists in acquiring an exact knowledge of the stone and the bladder, is one of the parts of the "ensemble" which influences most forcibly the success of the operation. The first step in advancing the science, then, is to make known the principles and means by which that knowledge is to be acquired.

OBSERVATIONS ON THE TYMPANUM, AS CONNECTED WITH DEAFNESS.

By JOSEPH SWAN, Esq.

(For the London Medical Gazette.)

It is not an unfrequent occurrence for deafness to be produced by very loud sounds, when the ear is unprepared for receiving them; but it is difficult to determine which part of the organ of hearing particularly suffers. I have thought that the injury was done principally to the tympanum, and this opinion is rendered very probable by the following case. I had seen the gentleman who is the subject of it; but as the facts are important, I prefer giving them in his own words:—

"In reply to Mr. Swan's questions, Captain Norton begs to state, that blood only came from the left ear, being in a right line towards the percussion; yet the singing or intense buzzing was equal in both ears—sometimes like the chirping of ten thousand sparrows, and at others a monstrous hissing. The first day Captain Norton could not hear any thing, and the second day could only hear a person who placed his mouth close to the ear, and spoke in a modulated tone; could not hear the high notes of a fife; could not distinguish the tune; he could not hear the boat-swain's call (whistle).

"Some four or five weeks afterwards Captain Norton was again in action, and was close to the muzzle of a gun when fired, and the report most com-

pletely restored his hearing for two days, when the singing again commenced. Captain Norton is of opinion that his hearing is as acute as ever, and it is only the singing which confuses sounds; for when one person only is speaking, he can hear him tolerably well; but when three or four are speaking at the same time, he cannot distinguish any one: he can hear a distant gun or bell as well as any one.

"Portsmouth, August 10th, 1829."

It must, I conceive, be admitted that the membrana tympani was ruptured in the preceding case, to have permitted the flow of blood from the left ear, and that the injury was almost entirely confined to the tympanum. Particular sounds could be heard, but words could not be sufficiently distinguished in a conversation carried on by several persons. These occurrences are very common in deafness, and arise very probably from the membrana tympani and the membrane of the fenestra rotunda not acting in unison. Hearing in the mammalia is, I presume, produced both through an impulse given to the labyrinth by the ossicula, and a modified one to the membrane covering the fenestra rotunda, so that particular sounds are heard through one of these parts and not through the other; for I cannot conceive that the membrane of the fenestra rotunda exists only for modifying the undulations conveyed through the labyrinth from the ossicula.

The membrane covering the interior of the tympanum, as well as that of the fenestra rotunda, may not be in a state for receiving properly the undulations from sound, as it may be thickened, and therefore incapable; or the functions of its nerves may have become impaired, so that its action cannot correspond with that of the membrana tympani; or the latter may alone be affected, whilst the other parts of the ear are healthy.

The membrane of the fenestra ovalis receives the undulations from the membrana tympani through the ossicula, and continues them through the semicircular canals and the scala vestibuli, as far as the apex of the cochlea, where they meet those imparted by the membrane of the fenestra rotunda to the scala tympani; therefore, unless the membrana tympani, and that covering the fenestra

rotunda, are in an equally perfect state, confusion of sounds must be the consequence, as the nerves spread on the whole labyrinth are so intimately connected that all the mechanical impressions made on them at the same instant must be in unison, or in such proportions as the original conformation of the labyrinth requires from its respective parts of the tympanum.

Some deaf persons cannot hear sounds that are either too high or too low, but only those that are moderate. I conceive that the several parts of the tympanum are in different states of activity in deafness, and presuming that some of the notes of music pass both through the fenestra ovalis and rotunda in modified degrees, and these two parts may be so influenced by any morbid changes as to prevent the production of motion corresponding with the degree of impression required in each of them for unison, the one must confuse or destroy the power of the other; and, therefore, if the voice or music be so managed as either to excite an equable action in both these parts, or be so adapted to one of them as quite to overpower or make no impression on the other, distinct hearing will be the consequence; and perhaps the motion of a carriage, by stimulating all the parts at the same time, produces that equable action which is necessary for fitting the deaf ear for hearing.

In the preceding case, on the restoration of the hearing for two days, the sound from the discharge of the gun acted as a stimulus to the membrana tympani and the nerves distributed in it and the tympanum. Whether the auditory nerves themselves were affected, must admit of some doubt. I have stated in a former paper, that these are not so often implicated as has been supposed; but that deafness, and the noises which accompany it, very often depended on the state of the nerves distributed in the membrane lining the tympanum. The auditory nerves themselves have very seldom been found defective or diseased, yet they may suffer either at their connexion with the brain, as when deafness is accompanied with epilepsy; or in their distribution in the labyrinth, in the same manner the optic nerves and retina do in amaurosis. But I wish to establish that, in a great proportion of habitually deaf people, these

nerves are not affected. If such conclusions lead to no improvement in the cure of deafness, it may appear a useless waste of time to enter into any discussion on the subject; but if a knowledge of the true seat of deafness be gained, a better mode of treating it will follow. If it be proved that deafness is most commonly seated in the tympanum, it is bringing the disease not only to a part more within our knowledge and nearer to the surface, through which remedies may be more efficaciously administered, but the very circumstance of its being within our reach, of its not being primarily seated in the brain and the delicate auditory nerves, may give reasonable ground for presuming that, although the nerves of the tympanum may be implicated, the diseases which involve them may be removed, and, by sufficient care, permanent deafness prevented. I conceive that the foundation of deafness is most frequently laid in childhood, and the inflammatory action which is its origin is not attended to, because it is merely ear-ache, discharge from the ear, &c.; but when this has once begun, exposure to cold, disorders of the digestive organs, &c. renew it, and in time the functions of the affected part become permanently impaired. It is an undoubted fact that modern surgery has prevented not only numerous operations, but deformities; because more care has been taken of incipient complaints, and a rational method of treatment has been adopted for their removal. Why should not this same care extend to one of the most exquisitely formed organs in the body—one on which so much of the comfort of man depends, and the loss of which is so deeply lamented by those who have experienced it? If when inflammation has been set up in the tympanum from any cause, means were taken to counteract its tendency to change of structure, and these were persevered in until the restoration of the organ became perfect, and a repetition of its exciting cause then obviated, why should not deafness be rendered less frequent, as well as blindness, and deformity from diseased joints?

OBSERVATIONS ON CATHETERISM,

OR THE

*Sounding which ought to precede the operation
for the Crushing of Calculi in the Bladder,
as practised*

By BARON HEURTELoup.

*To the Editor of the London Medical
Gazette.*

SIR,

THE following observations on "Catheterism" have been arranged from Baron Heurteloup's notes, and with his sanction. They have appeared to me to embody much valuable information. If you think them of sufficient importance to occupy a few columns of your Journal, they are at your disposal.

I am, Sir,

Your obedient servant,

J. RUTHERFORD ALCOCK.

September 24.

Previous to an operation for lithotomy, patients were always sounded, in order to ascertain with certainty the existence of a stone. To find the stone, and be convinced of its presence, was of great importance, since nothing short of certainty could justify the surgeon in making the patient run the risk of one of the most dangerous operations of surgery. That which was of the greatest consequence to the lithotomist, was first to prove the existence of the stone, and next to appreciate its size and form. As to its size, it was sufficient if he

could decide whether it was large or small—its intermediate condition could affect him but little: the only alteration would be his making his incision a little freer if it were of middling size. To the form and capacity of the bladder he paid little attention, for whether it was wide or narrow, deep or shallow, it could make little or no change in his mode of operating.

Hence it is that the lithotomist has never given any other form to the sound than that which he thought best adapted to the canal through which it had to pass. With this sound, to which he gave a large curve, he searched for the stone, and proved its presence by passing the convex edge over it, which was naturally parallel with the "bas-fond"* of the bladder, where the stone, on account of its weight, is generally situated. If at any time he wished to gain more precise knowledge respecting the stone, the extent of the curve given to the sound prevented the lateral movements necessary for that purpose; for its point being in contact with the superior surface of the bladder, it could neither be turned to the right nor the left.

As his only object was to prove the presence of the stone, the patient was ordinarily sounded without much water being contained in the bladder: if it happened to be full, he profited by the opportunity; but did not think this essential to the success of his research. To fill the bladder with water before he commenced sounding was not considered useful.

* This term here describes that part of the bladder which, whilst the patient is horizontal, is inferior to the cervix; and consequently includes the trigona and a considerable portion of the circumjacent bladder.

2 BARON HEURTELOUP'S METHOD OF PERFORMING CATHETERISM.

But if the *lithotomist* was not obliged to sound in such a way as to ascertain correctly all the particulars, it is absolutely necessary that the *lithotritter* should inform himself accurately of the state and form of the organ in which his instruments are to act, and of the stone against which the action of those instruments is to be directed.

After first discovering the stone, he must appreciate its size, density, nature, form, and position; ascertain the form and capacity of the urethra; the shape and size of the bladder—the greater or less regularity of its internal surface—the extent from the neck to the side—its depth below the neck—its width and power of contraction; for these are all circumstances the knowledge of which is essentially necessary to the lithotritter, and without which he cannot act with that certainty and precision which an operation requires, where its success depends on the strict observance of all the rules of prudence, the exact knowledge of the organ in which he is about to operate, and of the body which he is to destroy.

In the impossibility of obtaining all this with the sound generally used for this purpose, it was found necessary to give another form to the instrument, with which the exploration of the bladder might be conveniently made.

This instrument is a silver tube, two lines and a half in diameter, having a stop cock at the end, forming the handle. It is perfectly straight, and 8 inches in length to the commencement of the curve at the extremity. Its curve is exactly represented by the quarter of a circumference of a circle, the radius of which is an inch and a half. At the curved extremity there are two eyes, one at each side; and half an inch from its extreme point it screws off, that it may be cleaned with greater facility. The handle end is adapted for the reception of the pipe of the syringe, and, being lined with leather, fits sufficiently accurately to allow the injection of water to be made without any portion escaping by the side. The stop cock, which is inserted a little below the point of the syringe, by being turned, prevents the return of the fluid when enough has been injected; and with this instrument M. Heurteloup performs the sounding, which he designates the "Methodical Recto-curvi-linear Catheterism."

The Catheter, with the mouth to which the pipe of the syringe is adjusted when it is used. A little lower down is the stop-cock.

a This is to enable the pipe to be unscrewed when the syringe is cleaned.

M. Heurteloup's syringe is of silver, with the end of the piston forming a ring; there is also one at each side of

the neck. Thus the fore and middle fingers are introduced through the rings at each side, while the thumb is inserted in the ring end of the piston; so that the syringe can be held and the injection made with one hand, which has the great advantage of leaving the other at liberty to support and direct the sound*.

Such, then, are the two instruments by which the Baron sounds the bladder of a patient in which he suspects a stone, and when he is desirous of ascertaining the fitness of the case for operation. Before commencing the sounding process, he takes care to empty the rectum; because this intestine, according as it is more or less filled, alters the form of the bladder, and increases or diminishes its extent where they are in contact; and as it is precisely in this part of the bladder that the instruments are extended, it is evidently of importance. The patient is sometimes subject to internal hemorrhoids, and these may be so much developed as to project considerably, and consequently form indentations in that part of the bladder.

This precaution taken, and the patient placed on the side of his bed, flat on his back, the head a little raised, and each of his legs placed on a chair, the catheterism is effected with much gentleness. When the extremity of the sound is under the pubes, the curvature of this instrument being exactly adapted to the curve of the urethra from the pubes to the neck of the bladder, it is passed in by merely slightly depressing it. By continuing to depress the sound, and advancing it a little, the whole of the curved part is in the interior of the organ, while that which is straight is entirely in the canal.

From this moment M. Heurteloup is satisfied that the canal will allow the passage of a straight sound, for by the simple act of pushing the curve of the sound into the bladder, the whole of the urethra is brought into a straight line†.

In giving to the sound thus situated

* M. Heurteloup has called this the *surgical syringe*, to distinguish it from the ordinary syringe, which requiring the use of both hands, does not leave the left free.

† As soon as the sound has thus entered the bladder, the stop cock is turned, to allow all the urine in the organ to flow out, and he injects in its place warm water, until the patient feels a moderate desire to void it. The injection, and the consideration more particularly regarding it, are too long to be entered into here. It will be seen in this paper, that the bladder changes form in proportion as there is more or less water injected. There are certain laws respecting the

a slight movement forwards, he estimates, by the manner in which it is grasped, whether the introduction of the straight sound will be easy or difficult. If he can make this movement with the sound easily, it is a proof that the different parts of the canal may be brought into a straight line with facility; if, on the contrary, the sound is tightly grasped, it will be more difficult, and the operation probably more painful.

It must not be believed, therefore, that because the sound is grasped the passage is narrow, for this often happens in very large urethrae. The difficulty of passing it, which is sometimes considerable, depends upon each of the parts of the canal not being readily brought into a straight line.

When the canal is thus in a straight line, the greater or less play of the instrument depends on the degree of laxity of the parts, which give to the canal its natural curvature. When the straight part of the sound is in the full length of the urethra, the end in the bladder is carried upwards by the position of the neck, and equally upwards at the handle by the suspensatory ligament, while it is bound down below by the resistance which the pubes offers; and if the os pubis be very low, the suspensatory ligament very short, and a large prostate greatly raise the neck, these are sufficient reasons for the tight grasping of the sound; for, carried upwards at both extremities, and kept below by the pubes, it is not by the narrowness of the passage, but because it passes three points of the canal, which are brought with difficulty into a straight line, that the instrument is grasped.

When the sound is thus grasped it is an unfavourable condition, for the straight instrument will of necessity be introduced with greater difficulty, less easily suffered, and less easily manœuvred.

Hence he knows, as soon as he has moved the sound a few times forward and backward, if the crushing the stones will be easy or not, as far as the greater or less facility of the canal for the passage of straight instruments is concerned.

Besides ascertaining if the sound moves easily in the canal, he profits by these motions to find out what distance exists between the neck of the bladder and that part of its sides immediately opposite. This calculation is easily made in pushing the sound to the bot-

4 BARON HEURTELOUP'S METHOD OF PERFORMING CATHETERISM.

lom of the organ, and withdrawing it towards the neck: the play of the instrument allows the extent across to be easily ascertained, for the curvature being abrupt, the hooking it below the neck is very perceptible. This movement, therefore, enables him to decide whether the operation would be easy with regard to the extent from before backwards of the bladder. The facility of the operation will be in proportion to this extent, which varies ordinarily from two to four inches, but which is most generally from two inches and a half to three inches*.

By carrying the extremity of the sound from right to left, M. Heurteloup ascertains whether the bladder has sufficient width to allow the operation to be performed with facility. The extent in this direction the best adapted for the advantageous performance of the operation, is assuredly that which, at the same time that it gives sufficient room for the expanding of the instruments, is not so large as to allow the calculi or fragments to lodge themselves at the sides. The bladders which combine these two conditions are those in which the extent from side to side is three inches. It is desirable, then, for the surgeon to ascertain if the organ which he is

* It is this limited extent of the bladder from before backwards which renders the three-branch instrument, used for the destruction of calculi, often dangerous, the branches of which require to be extended a considerable distance beyond the tube, to seize a large stone: if these branches are too long, then it is impossible to manœuvre the instrument. It has been said that the three-branch instrument will seize large stones, and undoubtedly it can, but only by extending the branches very considerably beyond the extent of the external tube, which, it must be evident, renders the instrument inapplicable. It is true, if in drawing it against the neck of the bladder, efforts be made to seize the stone with the instrument "à trois branches," they would be successful, but he who thus operates no longer exercises an art, but a rude business. Nothing in this operation should be done by force; every movement should be skillfully performed, and consequently with gentleness. When it is recollected that these fatiguing and painful manœuvres which the surgeon is obliged to resort to, in order to seize a large stone with this instrument, only lead to the perforation of one hole, and that to make another the same steps must be taken, it will be a subject of surprise that any good surgeon should thus undertake to cure a patient afflicted with a stone of large dimensions.

These considerations induced M. Heurteloup to construct the "*Evideur* with *pince à forceps*." This instrument can be made to grasp, in the same manner as the forceps, large stones, with the branches projecting but a very short distance from the tube, and the branches being moveable separately allow the surgeon to seize the stone without injuring the organ: once grasped, it is scooped out until the sides break in; the fragments are then pulverized by the *bric à coudre*.

examining has this width. This information is easily acquired by means of M. Heurteloup's sound. The curvature of this instrument being the quarter of the circumference of a circle, the radius of which is one inch and a half; if it can be turned from right to left without the extremity coming in contact with the sides of the bladder, we must then feel convinced that it is three inches wide, since for an inch and a half at each side of the neck there is no resistance. It will be evident that the straightness of that part of the sound which is in the canal allowing the instrument to be turned on its axis, consequently permits the necessary movements to be given to the curved extremity. In order to ascertain the size of the bladder to its greatest possible extent, the Baron moves the instrument to the right and left several times, and at the same moment, by a movement forward, ascertains the depth of the organ from the neck to the part immediately opposite. He also ascertains, by moving the sound as far as possible to each side, if the bladder be much larger than the three inches he desires to find: if the beak of the sound does not touch the sides with facility, he concludes that the operation will probably require a longer time, for the fragments spread in the base of a larger bladder will no longer be placed so immediately under the branches of the instrument.

In these movements to the right and left and upwards he also determines whether the internal surface of the bladder presents many irregularities; as, for example, those fleshy columns which are often met with, and polypus excrescences which are sometimes found attached to the walls of the bladder, and particularly near the neck. It will be seen of how much importance it is to be aware of these excrescences, for they might get entangled with the branches of the instrument with which the operation is performed.

The extent of the bladder from the neck to the opposite side, and laterally, being ascertained, it then becomes necessary to know what is the depth from the neck to the "*basfond*." If the beak of the sound be turned downwards, this will be easily estimated; if it cannot thus be carried from right to left, the depth cannot be considerable, and it will be so much less in proportion as the sound is raised upwards to the level

of the median line. If, on the contrary, the sound turned downwards can be rotated without touching that part of the bladder which is below the neck, we are then sure there must be more than $1\frac{1}{2}$ inch depth, and this is an unfavourable circumstance, for the fragments will be seized with greater difficulty, or at least it will require the instrument to be inclined more perpendicularly downwards, which will be very painful to the patient. This depth below the neck is observed principally in spare subjects. M. Heurteloup provides against the inconvenience which it occasions by raising the pelvis considerably, which he easily effects by means of the little bed which he employs in his operations: when the pelvis is elevated, the fragment is displaced from beneath the neck, and is thrown into the base of the bladder, where it is seized with facility, and without pain to the patient.

During this manœuvre of the sound, which is to give the depth below the neck, M. Heurteloup observes in what degree the rectum projects against the bladder, for the state of this intestine, as has already been observed, influences much the greater or less facility with which the operation is performed. It is of importance, then, to know if this projection be considerable; and it is not until he is perfectly satisfied as to the exact form and dimensions of the bladder* that he directs his attention to the stone, and then the recto-curvilinear sound is greatly advantageous to the appreciation of this foreign body.

The ease with which this sound may be turned on its axis, and advanced or drawn back in the canal, is of wonderful service in acquiring the necessary information; for the facility with which the sound is moved allows the surgeon the full benefit of all the delicacy and precision of his movements.

As soon as M. Heurteloup proceeds to examine the stone, his movements become more gentle, for although, from the walls of the bladder being fixed, he allows himself to make his examination as to its dimension quickly, in order to abridge the catheterism, the mobility of the stone requires greater care; if the sound be manœuvred too quickly, the stone is moved, and does not permit the surgeon to ascertain its form, nature, &c. with precision.

* It may be conceived that this knowledge is acquired with great rapidity, for each movement of the sound gives a measure.

Whatever may be the size of the stone, it is always situated in the "bas-fond" of the bladder, when the patient is in the horizontal position. It is there, then, that he always directs his instrument. When it is found in any other part of the bladder, it is because the precaution has not been taken to inject it with warm water previous to the sounding, and that it is deranged from the place which it ordinarily occupies by the introduction of the catheter. Of course moveable calculi are alone alluded to here. If the stone be large, as it is generally placed on the median line, and that its size raises it on a level with the neck of the bladder, it is felt by the surgeon immediately the instrument is introduced, for the straight part of M. Heurteloup's sound is necessarily in contact with it.

The first thing he ascertains is the mobility of the stone, for on this depends whether it can be seized by the instruments. If he finds the stone immovable, and presenting an extended surface, he concludes that it is large, attached to the base of the bladder, and consequently not a proper case for the action of the lithotritic instruments: unless, indeed, the bladder should be very healthy, and easily dilated with a very large urethra, then the stone might be broken up with success; but these conditions are very rarely found with very bulky stones.

M. Heurteloup, however, before pronouncing this judgment, examines whether this immobility may not depend on the flat form of the stone; for, by this circumstance, a calculus, though not very large, is immovable, and seems to the sound, which merely passes over it, to present a large surface: to ascertain whether the stone is of this description, he carries the curve of the sound flat to the further edge of the stone, carrying the handle towards the thigh, to which the beak is turned: he thus encloses the stone in the curve of the sound, and getting it a little beneath the calculus, he raises it. If the stone is flat, it is raised with facility, and he feels that he could turn it over; if it is round, on the contrary, it may be raised, but it immediately falls back upon the sound*.

The contact of the sound with these

* Besides, the moment when the beak of the sound is pushed under the stone, he feels easily whether it is flat, by the slight distance the sound has moved from the upper to the lower surface,

6 BARON HEURTELOUP'S METHOD OF PERFORMING CATHETERISM.

large stones enables him to decide if they are smooth or rough, and whether they yield a clear or dead sound, circumstances which throw some light on the nature of the stone, and consequently the chances of success for the operation.

But, under any circumstances, those stones rendered immovable by their size are rarely adapted to the lithotritic process. Therefore, when their size is fully ascertained, it is of little use to continue the sounding.

When the stone is of moderate size, that is, when it is from 10 to 15 lines in diameter, the sound does not always meet it on entering the bladder: to find it, the instrument must be carried completely into the "basfond" of the bladder, the beak upwards; without this movement the stone will be immediately opposite the instrument, and according as its form allows it to roll with greater or less facility, it rests opposite the instrument, or rolls to one side. This motion of the stone is a favourable symptom, for it is rarely observed, except where the stone is nearly round, and this spherical form is of great advantage, and augurs well for the success of the operation.

If in carrying the point of the sound to that part of the bladder immediately opposite the neck, we do not find the stone, the sound must be drawn gently back, inclining it alternately to the right and left, and raising the handle a little so as to depress the neck of the bladder. In this manner it may be determined whether the stone is situated laterally or below the neck.

If it be situated laterally, it will be felt by the beak of the sound to one side or the other, and as the movement given is very gentle, the stone is not displaced but "caressed" by the instrument, which, on account of the facility with which it turns on its axis, allows the surgeon to follow the stone in all its contours, to measure it, move it, and ascertain its nature*. This movement,

which consists in carrying alternately the beak of the sound to the right and left, determines if the stone be situated laterally: if the sound, after having touched at the right, touches one to the left also, this double sensation is the certain indication of the presence of two stones in the bladder; for, if the base of this viscus be divided in two equal parts by the convexity of the curvature of the sound, and this convexity is not upon a stone, we are then certain that the double sensation is produced by two stones, and not by the alternate shock of the end of the sound on each extremity of a large stone. It is, nevertheless, almost impossible to be mistaken, for a large stone is always immovable, and placed centrally in the base, and stones so small as to be situated to one or other of the sides of the sound are moveable. It sometimes happens that we may convince ourselves of the existence of more than two stones, for after having felt a calculus to the right and another to the left, we find two in one or other of the sides, but the sensation obtained is too fugitive to enable us to decide whether there be three or four.

When a stone of moderate size exists in the bladder, and the sound does not meet with it either at the base of the bladder, opposite the neck, or laterally, it is situated under the cervix; and often, in drawing the sound back, raising the handle a little to depress the neck, M. Heurdeloup has felt the stone with that part of the sound where the curve ends in the straight line. In this case, as it is important to know whether the stone can easily be dislodged from its place, and also as it is necessary to displace it, in order to study it more effectively, he turns the beak of the sound towards the base of the bladder; and if this be deep enough below the neck to allow it to pass easily from side to side, the stone is easily removed, and he pushes it to the right or the left; and in order to keep it in that favourable situation, he depresses slightly the

and he then confines himself to this, without deranging it, which would give pain to the patient. He only displaces it when he is on the point of destroying it, which he does with the brise coque, the only instrument applicable to these kinds of stones.

* It is in stones of from 8 to 15 and 18 lines in diameter, that it is required to have their form, nature, and position, particularly ascertained; for it is in these kinds of stones that it is most generally necessary to apply the instruments, and in

which it is most difficult for the surgeon to determine on one system of destruction in preference to another. When the calculi exceed 18 lines in diameter, they no longer come under the class adapted to the action of the instrument; and when they are less than 8 lines, it is of little consequence what instrument is employed; they will be destroyed equally well with the brise coque or the instrument with three branches.

neck of the bladder with the convexity of the sound, so as to stop its return; for, whenever the stone is above the neck, it is almost impossible to gain an accurate idea of its form and size.

If the bladder should not be deep below the neck, there will be no necessity for turning the sound as has just been described; the simple introduction of it will displace the stone, and throw it off to the right or left. M. Heurteloup still alludes here to a stone of moderate size.

In fine, if the bladder contains one, two, or three small calculi—that is to say, of from four to ten lines—they will be rarely felt in the “*basfond*” of the bladder by the convexity of the sound; for, as soon as this part of it is carried to the posterior side, the small stone being generally light and rolling, it is moved with too much facility, and often rolls to the sides, and still more frequently below the neck. When it is placed in the lateral parts of the bladder, it is felt with the beak of the sound turned to the right and left; but the least movement, if not made with care, changes its position, and it is no longer touched by the sound. These movements ought to be more gentle and measured, in proportion as the stone is small.

When the stone is of small diameter, and is placed below the neck, it is felt with greater facility, whether the distance between it and the bottom be great or small: if there is but little depth, it is detected with the convexity of the sound, by raising the handle, and consequently depressing the neck; and if, on the contrary, the depth is considerable, the sound is turned so as to present the beak downwards; and as it can be rotated from side to side easily, the stone is certainly found, and its size and form easily appreciated. When the calculus is small, and wedged under the neck of a bladder of only moderate depth, it is touched by the sound with greater difficulty; for the convexity does not sufficiently depress the neck to touch it, and the beak turned downwards, coming in contact with the bottom of the bladder before it gets to the median line, where the stone is generally situated, cannot turn it over. In this case it is necessary to elevate the pelvis considerably; the surgeon will then be able to feel it with the convexity of the sound, for it is carried by

this position to a more distant part of the bladder, and consequently becomes more accessible.

When the bladder contains a great number of small stones, instead of three or four, the surgeon ascertains it very easily; for, collected together in the same part of the base of the bladder, the stones, when moved, convey a sensation produced by their collision against each other.

It sometimes happens, when there is but one stone and it is very small, that it escapes the most methodical researches: it is then useful, when the symptoms leave little doubt as to the existence of a foreign body, to introduce a “*pince à forceps*,” which is better adapted to discover a stone when it is of this small size, and permits the surgeon to seize and crush it, which converts the sounding into an operation very advantageous to the patient. M. Heurteloup has in this manner cured some patients who had small stones, which, by their great mobility, escaped the touch of the sound but not that of the pincers, which indicated their presence, and seized them at the same moment. In these cases of small stones, the “*pince à trois branches*” is a most useful instrument, and it was by no means with a view to supersede its use in these cases that Baron Heurteloup undertook his labours.

Such are the data which the lithotritter ought to possess before he commences the operation, and such are the means of quickly acquiring, with mathematical exactness, a knowledge of the organ in which he is going to manœuvre his instruments, and the bodies on which he is to make them act.

When the science only possessed the “*instrument à trois branches*” of MM. Leroy and Civiale, to arrive at the desirable result of curing calculous patients without an incision, it was, perhaps, less useful to the surgeon to appreciate with accuracy the form and size of both bladder and stone—since this instrument was applied in all cases, against large or small bodies, round or flat, a wide or narrow bladder: the surgeon having only one instrument, had no choice to make. But now, that different mechanical means of destroying the calculi have multiplied the chances of success, and extended the limits of the lithotritic art, it will be evident how important it is to be accurately informed of the different circumstances of each case,

of a profession of which he will then have become an ornament and a support. Let him follow the example of John Hunter, of whose life we have inserted a sketch, for the express purpose of calling the attention of our younger friends to the manner in which that truly great man raised himself above all his fellow students, by the indefatigable zeal, industry, and talent, with which he met all the difficulties opposed to his advancement.

MIDDLESEX HOSPITAL.

WE beg to direct attention to the contradiction of some falsehoods in the *Lancet* of last week, with regard to this Hospital. We have made inquiry, and find that the statement as to pupils, contained in a letter in our present Number, signed "John Middlesex," is correct.

ST. GEORGE'S HOSPITAL.

THE south wing of this magnificent structure has been finished for some time, and is now filled with patients, in addition to those who are still received in the old building. The new wards are lofty and commodious, and calculated to afford every comfort to the patients that their situation admits of. A theatre for pathological examinations has been constructed, and the whole arrangements are such as will render this Hospital one of the most complete in the metropolis.

LONDON UNIVERSITY—MR. BELL'S INTRODUCTORY LECTURE.

October 1, 1839.

MR. BELL was received, by a crowded audience, in a manner worthy of the body whom he represented, and of his own individual rank as a man of science, as well as an experienced and popular teacher. We regret that neither time nor space admits of a *verbatim* copy of his lecture, but we subjoin a copious abstract, embracing the principal points.

Mr. Bell began with the only remark in which he did not carry with him the feelings of his hearers. "I (said the professor) am known only by the work of my hands, and I cannot but re-

gret that the honour of addressing you has not fallen on some of my more learned colleagues."

The lecturer in the first place alluded to the eminence of the private teachers of medicine in London, and the zeal they displayed in maintaining their schools. He hoped that the foundation of this university did not tend to discourage private teaching, but rather to raise it to greater respectability, and that if it threw difficulties in the way of those embarked in teaching, at their commencement, it would promise them more honour in the sequel.

He then took a view of the origin of other universities, remarking their connexion with the church, and the eminent services they had rendered. To them every Englishman was largely indebted. "The extension of his language (said the lecturer) over half the globe, and the wide spreading influence of his country's laws and customs—a conquest which makes none to mourn—was most of all to be attributed to the early and continued labours of those ancient establishments for learning. But when we consider the new objects which have arisen in our day, and especially the necessity for encouraging high professional attainments, new institutions must arise with the occasion for them." He then showed the necessity of a more intimate blending of science with education than exists in the systems of the old universities. In a review of the Scottish seminaries, he pointed out the differences in their foundations arising from the events of the reformation, and the peculiar church government of Scotland. They are less under the restraint of church discipline, have fewer livings to bestow, and no patronage in the church. By whatever means it happened, he remarked, discoveries in science have ever found immediate countenance, and zealous and ardent prosecutors in these universities. They have stood foremost among the schools of Europe for the ready encouragement of every improvement. In morals and in metaphysics the names of Hutchinson and Adam Smith, Reid and Stewart, must ever be remembered with gratitude. In mathematics and physics, the Gregorys, MacLaurin, Simson, and Playfair, rank high; whilst in chemistry and in medicine, the fame of Black and Cullen, and the Munros, has spread wherever these

sciences are known. But it would appear that these universities have retained so much of their ancient and too formal constitution as to require periodical visitations and reforms,—as in the royal commission now sitting for the revival of the universities in Scotland.

The lecturer in the next place drew attention to the excellency of the constitution of the London University, and the means which it possesses of accommodating itself to the necessities of the times without any violent revolution. The peculiarity to which he alluded might be referred to two causes. 1. The extensive connexion which is necessarily maintained between this institution and a vast body of the public, by means of the numerous shareholders. Even by the tie of property, but much more by the regard which they must have for the education of their children, all those persons are deeply interested in seeing that this university shall continue to cultivate in the best and most approved manner the learning, sciences, and arts, which are useful to men engaged in the pursuits of active life. But—

2. The institution is not left to the popular impulse of so large a body. This impulse, while it serves to give the spirit of improvement, is under the immediate direction of a council, by whom the whole machinery is guided. This council consists, not of men suddenly raised to the exercise of power, and liable to abuse it from its novelty, but of men who are accustomed to exercise their talents and zeal in higher places; and who, in fact, descend to most painful minutiae when they give up their higher occupations to assemble here.

In this constitution there is a perpetual source of activity; a connexion with the better and wiser part of society; a participation of the influence of practical men—with men of rank and of genius; an arrangement which, in every succeeding year, will add to the usefulness, and consequently the reputation, of the university.

The members of the council sit before their professors on many occasions, hearing the examinations of the pupils, marking their progress, and observing the effects of the modes of teaching;—thus, as it were, partaking of the labours of the professors, and participating in their anxieties, so that they are well prepared to judge of what is best for the institution and the public.

The ambition of the student is highly

excited by feeling that his efforts are not to be made in solitude and obscurity, but that his successful exertions are noticed, and that distinction awaits him. It was to be expected, when men of the first rank and genius became the patrons of this university, that the influence would spread, and that others would lend their aid in so meritorious a work. It is with great pleasure, therefore, that he had to announce that the right honorable Charles Wynne had presented, for the disposal of the council, a surgeoncy in the Honorable East India Company's Service. It required no great prescience to foretell the happy consequence of this. When men of influence consider how often they are betrayed into giving a provision for the very least deserving, he hoped that they might see the virtue of aiding the council in their exertions for the public service, through rewards bestowed on individual merit.

In regard to the professors, he remarked, that it is an unspeakable advantage in such institutions that there is a force silently but incessantly operating towards improvement in the art of teaching. Without taking from him that highest privilege which belongs to a zealous professor—the credit of improving the methods of teaching and extending his course—the presence of the council must keep alive the spirit of emulation. There is no necessity for those periodical and almost violent interferences by means of college discipline, which scarcely ever fail to occasion unpleasant feelings when new codes and regulations are enacted legislatively by a special commission. Contrasted with this, the arrangement in this university leads to reformation by degrees, gently, and without offence. Whatever is amiss is at once put into a course of amendment: it is an effect like that perpetual watchfulness of the public mind maintained by means of a free press over all national councils; and which is at once the most vigilant to correct negligence and error, and the most efficacious in reformation.

The lecturer, after some further observations, proceeded to say, that if, in the constitution of other universities, as compared with this, there was reason for them to congratulate themselves, so there was also reason to rejoice in the time and place, and circumstances, in which their efforts were to be made.

As to time, there was a change in the

public mind, from that which characterized it in the preceding age, the result of the eventful period in which we have lived. The rise and fall of great men, and the revolutions of nations, have been crowded into so small a space of time, that the moral may be drawn as from a drama; and men have witnessed tragedies, with so much resemblance to the rapid shifting of a scene, that they have actually complained that the great have fallen in the course of nature, and not, according to the dramatic rule, by their own hand. Whilst, amidst all these feverish changes of opinion, the advantages of the ancient institutions of the country, in giving security against too rapid innovation, is deeply felt, there has arisen a sentiment almost universal, that education is the best foundation of sound principles, and that, if knowledge had been more general, much of the evil would have been prevented which has been witnessed in our days.

As to place, there are certainly some people (those who lead retired lives) who imagine that vice reigns triumphant in London, and who indulge the thought that purity and peace inhabit the thatched cottage in the retired fields and woodlands. But wiser men say that both are exaggerations, and that every where vice and misery dwell with ignorance. If there be disadvantages in the education of youth in London, these disadvantages may be foreseen and obviated; but, on the other hand, how great are the advantages! What man of science, or learning, does not seek, as it were, his kindred, in London? Who does not pine for the advantages which men may here enjoy, in our museums, libraries, gardens, and learned societies? But there is another advantage to the University which must not pass unnoticed. When the professors shall, by a double portion of labour, have established their several classes, the Council may call learned and ingenious men from all parts of the world, to raise the character of this school to a height which, seeing it only in the labours of the present professors, can hardly be estimated. Witness what Edinburgh has done, being a capital. Its professors were not all formed there. The celebrated Black was a professor in Glasgow. Dr. Cullen, to speak whose eulogy would be super-

fluous here, was also a professor in Glasgow, and his reputation was high, as a teacher, before he was drawn to Edinburgh. The elder Gregory was professor in the College of Aberdeen. The present celebrated professor of chemistry in Edinburgh was also drawn from another University; and Dr. Chalmers, the ornament of the Scottish church, was professor in St. Andrew's before he was appointed to his present chair.

Here, then, (said Mr. Bell) you see the attraction which learned men have to the seat of learning; and so, with the thousand greater attractions of London, this University, once established, and the Council which watches over it, will have a more extensive patronage over learned and ingenious men, than ever fell to the lot of any similar society.

But looking to the immediate interests of the students—putting aside the well-ordered courses of study, which nowhere besides in this country can they command—the combination of classes under the same roof, and the provisions for private study in the intervals of lecture—what is it that attracts the attention of a well-educated youth out of the University? That which should confirm him in his best resolutions, and strengthen his highest aspirations. To see to what dignity great talents highly cultivated raise a man, in a free state—to see the eminence of our Judges, or to witness the force of eloquence in the Courts—by these an indelible impression must be made upon his mind of whatever is truly excellent and worthy of imitation. Or he takes another course: Let him visit the hospitals, and learn, perhaps, what course of life will best accord with his sense of duty and virtue. He may see that in the office of the physician there is a nearer correspondence with what religion and humanity dictate, than in any other profession—a course of life always respectable, which will at no time want interest, and which will appear the more honorable the nearer he approaches to the end of life.

The next division of the lecturer was occupied in giving an account of the Medical School: and he contrasted the necessity of a complete system of medical education, with the entire devotion to surgery, which is remarkable in some other schools. He concluded with the following address to the students:—

"And now let me address a very few words to those younger gentlemen, who, to use the French phrase,—*assist* at the lectures delivered here. It requires not the use of the major and minor proposition to demonstrate that we cannot do without them. But in declaring the students a constituent part of this University, let me remind them how much depends on them. I shall not point out to them a selfish view, by declaring their own interests involved, and the happiness of every one dear to them: I shall merely state to them that there is a more manly and inspiring object which we expect to move them.

"I fear it cannot be concealed that there are some, a very few, whose prejudices are morbid, and desperate, beyond hope, to whom it would prove no disappointment if all that has been done for education in this place were to prove abortive. No sign of this would be seized upon with more reckless and mistaken zeal than any thing like incorrectness in the conduct of the students. I beg of you therefore individually to consider, that you are embarked in a great measure, which gives the most lively anticipations of high national advantage, and that even by the misconduct of the least of you that hope may be disappointed; that just as there are many great and good men prepared to hail with acclamation every successful student, so must their disapprobation and their disappointment be strongly felt, if misconduct should injure this young establishment.

"But let me again say, that neither Professors nor Students have ground for any such fear; on the contrary, every thing declares the permanency of the benefits which this University is capable of conferring. And we must carry ourselves here as in Ancient Rome, where it was regarded as the mark of a good Citizen never to despair of the fortunes of the Republic."

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, Esq. F.R.S.

LECTURE I.—Oct. 1st.

[The theatre was crowded to excess, and Mr. Lawrence was greeted on his appearance

with all the enthusiasm which pupils usually shew towards an eloquent and favourite teacher.]

GENTLEMEN,

AFTER teaching anatomy and surgery for upwards of forty years in this hospital, and I believe never failing once during that period to open the course of winter lectures on the 1st of October, Mr. Abernethy is no longer able to continue those labours which have raised the medical school of this hospital to so high a reputation, and contributed so signally to elevate and advance the profession of surgery. The strength of intellect which distinguished our great teacher was manifested at an early period of his career. He began to teach his profession at a time when others are usually employed in learning it—that is, at the expiration of his apprenticeship. Soon after, he presented the world with those essays which placed his name in the first rank of physiologists. The original train of thinking, and the great talents for observation, which he evinced at this early period, gave birth to anticipations which subsequently were fully realized. His very high character, both as a writer and a teacher, is so well known, and so generally appreciated, that I need not enlarge upon the subject—particularly in this theatre. I will take this opportunity, however, of saying that we may ascribe to him the great merit of having been the first to introduce a more general and scientific investigation of the principles of surgical science. He was among the first in this country to assert the rank of surgery. He taught us to raise our views beyond the narrow limits of local disease. He has been regarded on this account as a kind of intruder on the province of physic, and as having entertained a wish to make surgeons—physicians. If it be meant by this charge to accuse him of entertaining a wish that surgeons should add to their surgical knowledge that of medicine, the accusation is just, and in my opinion does him great credit. By inducing surgeons to study medicine generally, and thus reuniting two separate parts of one great subject, he has at the same time signally benefited the public, and conferred honor on his own profession.

The departments of Anatomy and Surgery, which were held conjointly by Mr. Abernethy, are now undertaken separately by Mr. Stanley and myself. It will be our business to keep steadily in view the example of our great predecessor. However far behind him we may be in the powers of acquiring and imparting information, we will not acknowledge any inferiority in one respect—that of an earnest desire to render ourselves useful to our pupils (*cheers*), and of holding a firm determination to discharge

the duties we have undertaken to the best of our ability. This change, however, will make some alteration necessarily in the arrangement of the lectures. When Mr. Abernethy undertook both departments, he could distribute the subjects as he pleased between the two courses: he found it convenient, or thought it expedient, to introduce a considerable part of the subject of Surgery into the Anatomical Lectures. When I say a considerable part, I might say one-half or two-thirds, including the performance of operations, and the states in which such operations are necessary,—the diseases of the bones,—the accidents to which they are liable;—the injuries and diseases of the joints,—and many other subjects. We shall allot to each department the diseases which properly belong to it; and as I purpose to go through the whole of Surgery, it will not be practicable for me to give you two courses of lectures. We shall find that the subjects are so extensive and so numerous, that they will fill one course, lasting through the whole of the winter. I purpose to lecture on Surgery three times a week; and I conclude that this arrangement will allow sufficient time for including every thing that belongs to the course. In the prosecution of this design, I shall commence at seven o'clock to-morrow evening with the proper business of these lectures.

Surgery is one division of the science and art which have disease for their object. The science, considered generally, embraces the physiological history of man. It investigates, in the first place, the construction and living actions of the human frame. It inquires into the purposes executed by each part of the body, and into the general result of their combined operations. It surveys the human organization under all the various modifications which are impressed upon it by surrounding influences, and draws from these several sources the rules to be employed in preserving health and removing disease. The practical application of these rules constitutes the art of healing, or rather of treating diseases: for in many cases we are unable to heal, and do not even attempt it. The assemblage of facts and reasonings on which these rules are grounded constitutes one science; and the boundaries of surgery have not hitherto been, nor perhaps can they be, accurately defined.

For my own part, I take the word surgical in the common acceptation, understanding it to include injuries of every description,—all the external local diseases,—such internal diseases as produce changes recognisable externally—such as require in their treatment topical operations and manual proceedings.

The subjects I have just enumerated form the catalogue which is treated of in the surgical writings of Mr. Sam. Cooper. It is of the

same kind of subjects that Boyer and ~~W~~pech treat, when speaking of external diseases. The title adopted by the latter is, "Treatise on Diseases reputed or considered to be Surgical."

There has been as much difficulty experienced in France as in this country, in defining the limits between the two professions. I am convinced that the boundary, as now fixed, is not very clear, and the consequence is, that great disputes have arisen. Operations, injuries, and external local complaints, are the undisputed possession of surgery, and internal diseases are assigned to the physician. But it is not easy to distinguish between external and internal diseases; here in fact surgery and physic join. Since it is found thus difficult to draw a satisfactory line of demarcation between physic and surgery, you will not be surprised to find, in a great majority of instances, that both are practised together in this country by one description of persons, surgeon-apothecaries. Nineteen-twentieths of diseases are under the care of this class of persons in the country, who are therefore styled general practitioners. On the other hand, in the metropolis, we find that these two branches of the profession are exercised by a different class of persons, whose education differs widely in some important points. We find it taught by separate teachers, in distinct courses of instruction; and we find this regulation enjoined by the laws of two distinct incorporated bodies.

Finding these contradictions, we are led to inquire more particularly into the distinctions between physic and surgery—to ask whether it consists in the nature of the disease allotted to each, or in the mode of treating it—to inquire whether there is any difference in the mode of learning them—to ask how and when the distinction originated, whether it is well founded, whether it is of any benefit to the public or any advantage to the practitioner? Nothing like the modern distinction was known to the ancients; at least we find no traces of it in the Greek, Roman, or Arabian writers. Particular branches of medicine were, indeed, followed separately in Egypt, where the diseases of the eye, and some internal organs, formed the distinct occupation of different practitioners; and a distinction somewhat similar is said to have prevailed at Rome. But Hippocrates, Galen, and Celsus, treat of the nature and management of fever, of injuries, and of external and internal complaints in common. Celsus, in speaking of the treatment of diseases, distributes what he has to say under three divisions, the same as are this day employed—*διατηρητικη*, *φαρμακευτικη*, and *χειρουργικη*—according as the treatment is to be accomplished by dietetical, pharmaceutical, or surgical means. But the idea of splitting medicine into two

parts, and learning the practice separately, seems never to have been entertained by this writer, nor any other great author whose name is still regarded as authority.

In the long night of barbarous ignorance which intervened between the downfall of the Roman empire and the revival of learning in the West, the treatment of diseases was preserved by the ecclesiastics. The exercise of medicine harmonized well with the more immediate object of their calling. But when the Council of Tours had declared—*ecclesias abhorret a sanguine*—that the church was defiled by blood, the priests and monks could no longer use any of those means that involved the loss of blood, and the practice was taken up by infidels and itinerants. In the course of time, surgery, which then consisted merely of bleeding and tooth-drawing, fell into the hands of a few persons who practised these in conjunction with the trade of the barber, and which ultimately led to the incorporation of the barbers and surgeons into a company. This separation of surgery from that medical knowledge which is an indispensable guide to its proper application, and its union with the art of the barber, long survived the circumstances that gave rise to it. It continued in this country till the middle of the last century, when it was dissolved in the reign of George II. The combination of the two branches still remains in many parts of Europe.

In order to determine whether there is any real ground of distinction between physic and surgery, it is necessary to advert to the general practice of both. The individual organs which make up the human body, although various in their structure and office, are all intimately connected with, and dependent upon each other. They are subordinate parts of one great machine, and all concur in one common object—the life of the individual. All the leading arrangements are calculated to give a character of unity to the organic and living actions of the body. There is one source of nutrition of the whole frame; there is one centre of circulation; there is a common place of union of all senses and volition—a common centre of nervous energy. The various organs are not only intimately connected but act on each other by a mysterious, or at least hitherto unexplained cause which is denominated sympathy. Every part composing our frame acts dependently; all the parts are immediately or remotely connected; and hence you could form no adequate idea of the sympathies of the organs if you insulated them from the rest any more than you could estimate the use and action of a single wheel or lever detached from a watch or steam engine. As a united machine, though complicated, is essential to accomplish the end for which it is formed, so living actions, although numerous and intricate, form an

indivisible whole. Hence there is one anatomy and one physiology, and there can be only one pathology. If you wish to understand any part, you must not only examine the part itself but must survey the whole. In the same way, if you wish to investigate disease, you must observe not only the local affection, but the influence that other parts may exert over the seat of the complaint.

It must be the first business of the medical student to examine the structure and living actions of the frame; that is, to study man in a state of health. These are the objects of the two sciences, which are denominated Anatomy and Physiology. He then proceeds to observation. He notices the circumstances under which disease arises; he watches its progress, and its termination; he explores the organic changes it produces after death; and learning to connect these with the appropriate external signs by which the disease is accompanied, and deriving from these comparisons the means of ascertaining the exact seat of the disease, he is able to foretell its course and termination. This forms the subject of two other branches, which are distinguished by the names of Morbid Anatomy and Pathology. Morbid anatomy is opposed to anatomy; pathology is opposed to physiology. Anatomy regards the healthy structure; morbid anatomy the diseased one. Pathology regards the diseased functions; physiology those that are healthy. The student is now prepared to apply the external influences, such as diet, climate, exercise, the outward or inward remedies, or the surgical operations which may be necessary for the removal of disease, and the restoration of health. The real question relative to the distinction between physic and surgery, then, comes to this: after treating disease generally, in the way just mentioned, can you discover any portion of it insulated from the rest? Can you find out any division that can be undertaken without a reference to other parts? Can you divide the subject of disease into two classes that may be treated in a different manner? Certainly not. The structure and functions are universally connected; no part is independent. The causes that constitute disease are often to be found, not in the part itself, but in a remote portion of the frame; the means of cure are seldom to be applied actually to the part diseased: for instance, if a person has a gouty inflammation of the toe, no cause of disease can be ascribed to the part itself; but if you examine the state of the individual, you will find a full and strong pulse, and other marks indicating a fulness of habit, or plethora, as it is called; the tongue will indicate a disorder in the digestive organs, and your treatment must consist in adopting the means necessary to remove the fulness of habit, and to correct the digestive organs, and the patient goes on well without

the duties we have undertaken to the best of our ability. This change, however, will make some alteration necessarily in the arrangement of the lectures. When Mr. Abernethy undertook both departments, he could distribute the subjects as he pleased between the two courses: he found it convenient, or thought it expedient, to introduce a considerable part of the subject of Surgery into the Anatomical Lectures. When I say a considerable part, I might say one-half or two-thirds, including the performance of operations, and the states in which such operations are necessary,—the diseases of the bones,—the accidents to which they are liable;—the injuries and diseases of the joints,—and many other subjects. We shall allot to each department the diseases which properly belong to it; and as I purpose to go through the whole of Surgery, it will not be practicable for me to give you two courses of lectures. We shall find that the subjects are so extensive and so numerous, that they will fill one course, lasting through the whole of the winter. I purpose to lecture on Surgery three times a week; and I conclude that this arrangement will allow sufficient time for including every thing that belongs to the course. In the prosecution of this design, I shall commence at seven o'clock to-morrow evening with the proper business of these lectures.

Surgery is one division of the science and art which have disease for their object. The science, considered generally, embraces the physiological history of man. It investigates, in the first place, the construction and living actions of the human frame. It inquires into the purposes executed by each part of the body, and into the general result of their combined operations. It surveys the human organization under all the various modifications which are impressed upon it by surrounding influences, and draws from these several sources the rules to be employed in preserving health and removing disease. The practical application of these rules constitutes the art of healing, or rather of treating diseases: for in many cases we are unable to heal, and do not even attempt it. The assemblage of facts and reasonings on which these rules are grounded constitutes one science; and the boundaries of surgery have not hitherto been, nor perhaps can they be, accurately defined.

For my own part, I take the word surgical in the common acceptation, understanding it to include injuries of every description,—all the external local diseases,—such internal diseases as produce changes recognisable externally—such as require in their treatment topical operations and manual proceedings.

The subjects I have just enumerated form the catalogue which is treated of in the surgical writings of Mr. Sam. Cooper. It is of the

same kind of subjects that Boerhaave and Hallpech treat, when speaking of external diseases. The title adopted by the latter is, "Treatise on Diseases reputed or considered to be Surgical."

There has been as much difficulty experienced in France as in this country, in defining the limits between the two professions. I am convinced that the boundary, as now fixed, is not very clear, and the consequence is, that great disputes have arisen. Operations, injuries, and external local complaints, are the undisputed possession of surgery, and internal diseases are assigned to the physician. But it is not easy to distinguish between external and internal diseases; here in fact surgery and physic join. Since it is found thus difficult to draw a satisfactory line of demarcation between physic and surgery, you will not be surprised to find, in a great majority of instances, that both are practised together in this country by one description of persons, surgeon-apothecaries. Nineteen-twentieths of diseases are under the care of this class of persons in the country, who are therefore styled general practitioners. On the other hand, in the metropolis, we find that these two branches of the profession are exercised by a different class of persons, whose education differs widely in some important points. We find it taught by separate teachers, in distinct courses of instruction, and we find this regulation enjoined by the laws of two distinct incorporated bodies.

Finding these contradictions, we are led to inquire more particularly into the distinctions between physic and surgery—to ask whether it consists in the nature of the disease allotted to each, or in the mode of treating it—to inquire whether there is any difference in the mode of learning them—to ask how and when the distinction originated, whether it is well founded, whether it is of any benefit to the public or any advantage to the practitioner? Nothing like the modern distinction was known to the ancients; at least we find no traces of it in the Greek, Roman, or Arabian writers. Particular branches of medicine were, indeed, followed separately in Egypt, where the diseases of the eye, and some internal organs, formed the distinct occupation of different practitioners; and a distinction somewhat similar is said to have prevailed at Rome. But Hippocrates, Galen, and Celsus, treat of the nature and management of fever, of injuries, and of external and internal complaints in common. Celsus, in speaking of the treatment of diseases, distributes what he has to say under three divisions, the same as are this day employed—*διατηρητικη*, *φαρμακευτικη*, and *χειρουργικη*—according as the treatment is to be accomplished by dietetical, pharmaceutical, or chirurgical means. But the idea of splitting medicine into two

parts, and learning the practice separately, seems never to have been entertained by this writer, nor any other great author whose name is still regarded as authority.

In the long night of, barbarous ignorance which intervened between the downfall of the Roman empire and the revival of learning in the West, the treatment of diseases was preserved by the ecclesiastics. The exercise of medicine harmonized well with the more immediate object of their calling. But when the Council of Tours had declared—*ecclesias abhorret a sanguine*—that the church was defiled by blood, the priests and monks could no longer use any of those means that involved the loss of blood, and the practice was taken up by infidels and itinerants. In the course of time, surgery, which then consisted merely of bleeding and tooth-drawing, fell into the hands of a few persons who practised these in conjunction with the trade of the barber, and which ultimately led to the incorporation of the barbers and surgeons into a company. This separation of surgery from that medical knowledge which is an indispensable guide to its proper application, and its union with the art of the barber, long survived the circumstances that gave rise to it. It continued in this country till the middle of the last century, when it was dissolved in the reign of George II. The combination of the two branches still remains in many parts of Europe.

In order to determine whether there is any real ground of distinction between physic and surgery, it is necessary to advert to the general practice of both. The individual organs which make up the human body, although various in their structure and office, are all intimately connected with, and dependent upon each other. They are subordinate parts of one great machine, and all concur in one common object—the life of the individual. All the leading arrangements are calculated to give a character of unity to the organic and living actions of the body. There is one source of nutrition of the whole frame; there is one centre of circulation; there is a common place of union of all senses and volition—a common centre of nervous energy. The various organs are not only intimately connected but act on each other by a mysterious, or at least hitherto unexplained cause which is denominated sympathy. Every part composing our frame acts dependently; all the parts are immediately or remotely connected; and hence you could form no adequate idea of the sympathies of the organs if you insulated them from the rest any more than you could estimate the use and action of a single wheel or lever detached from a watch or steam engine. As a united machine, though complicated, is essential to accomplish the end for which it is formed, so living actions, although numerous and intricate, form an

indivisible whole. Hence there is one anatomy and one physiology, and there can be only one pathology. If you wish to understand any part, you must not only examine the part itself but must survey the whole. In the same way, if you wish to investigate disease, you must observe not only the local affection, but the influence that other parts may exert over the seat of the complaint.

It must be the first business of the medical student to examine the structure and living actions of the frame; that is, to study man in a state of health. These are the objects of the two sciences, which are denominated Anatomy and Physiology. He then proceeds to observation. He notices the circumstances under which disease arises; he watches its progress, and its termination; he explores the organic changes it produces after death; and learning to connect these with the appropriate external signs by which the disease is accompanied, and deriving from these comparisons the means of ascertaining the exact seat of the disease, he is able to foretell its course and termination. This forms the subject of two other branches, which are distinguished by the names of Morbid Anatomy and Pathology. Morbid anatomy is opposed to anatomy; pathology is opposed to physiology. Anatomy regards the healthy structure; morbid anatomy the diseased one. Pathology regards the diseased functions; physiology those that are healthy. The student is now prepared to apply the external influences, such as diet, climate, exercise, the outward or inward remedies, or the surgical operations which may be necessary for the removal of disease, and the restoration of health. The real question relative to the distinction between physic and surgery, then, comes to this: after treating disease generally, in the way just mentioned, can you discover any portion of it insulated from the rest? Can you find out any division that can be undertaken without a reference to other parts? Can you divide the subject of disease into two classes that may be treated in a different manner? Certainly not. The structure and functions are universally connected; no part is independent. The causes that constitute disease are often to be found, not in the part itself, but in a remote portion of the frame; the means of cure are seldom to be applied actually to the part diseased: for instance, if a person has a gouty inflammation of the toe, no cause of disease can be ascribed to the part itself; but if you examine the state of the individual, you will find a full and strong pulse, and other marks indicating a fulness of habit, or plethora, as it is called; the tongue will indicate a disorder in the digestive organs, and your treatment must consist in adopting the means necessary to remove the fulness of habit, and to correct the digestive organs, and the patient goes on well without

any application to the toe. Another person may have a paralytic affection of his finger, and you can discern no cause for it in the part itself; you will find every thing in the paralyzed member perfect as to structure; but on examination, you find disease existing in the head; you take the means of allaying that disease, and then the paralyzed parts recover the power of motion. In many cases, disease originating in one part affects a great many other organs of the body; and very often the secondary disease thus produced attracts more attention than the original complaint itself. A person has an affection of the head, which may be produced by various causes, and within a short time, the circulating system, the digestive organs, and the secretions, become deranged, and he is in a state of continued fever,—another individual receives an injury,—inflammation is set up in the part, and in a short time the same febrile disturbance arises. The patient has a sympathetic fever in both cases, and the latter disease seems of more consequence than the former. Again, although individual organs are numerous, the components of organic structure in the body are few; the different proportions in which they enter into the composition of parts, is what makes the difference, just as the combinations of a few letters give the infinite variety of words. When you have arranged and divided the causes of disease into two halves, you may give those different names, and require that they should be practised by different individuals, but the two divisions that you establish will be like each other, and the cause and the treatment of disease will in both cases be exactly similar. If you will insist on a distinction, it must be arbitrary. Then you can establish it clearly. You may divide diseases into those of the right side and of the left, or into those of the upper and lower halves of the body.

To assert that surgery and physic are essentially distinct, would be to say that there are two descriptions of pathology—that the external and internal parts of the body were to be treated on different and distinct principles. When you reflect that the primary tissues composing the various organs of the body are the same throughout, and that the difference consists solely in the number and proportions of those tissues, you will see that the various parts of the body cannot alter the nature of the disease, though perhaps there may be a difference in the mode of its treatment;—the way in which it is to be carried into force may be varied, because local applications may be made to the external parts which cannot be done to those that are internal. We treat the disease in the same manner, whether it is in the eye, the breast, the testicle, the heart, the lungs, or the liver. The princi-

ples of pathology, therefore, are general; they are the same in all parts of the body; and they must be common to the physician and the surgeon. Hence we may say, as Mr. Abernethy has most justly done, that surgery and physic, considered as objects of scientific information, are one and indivisible. We may with great propriety affirm that no single branch of medicine can be acquired except by those who have studied the structure of the whole frame.

By those who are inclined to defend existing distinctions, various views have been taken as to the ground on which they ought to rest: for example, external diseases have been referred to the surgeon; those that are internal to the physician. But, unfortunately for this distinction, nature has connected the outside and the inside of the body so closely that it is impossible to say where the one terminates and the other begins. If we were to adopt this distinction we should consider how far the exterior of the frame extends, and how far the province of the surgeon is to go; whether it is to extend half an inch into the body or an inch? What is the boundary of the internal cavities and of the external outlets: for example, those lined with mucous membrane? The distribution of disease between the physician and surgeon seems to be absurd. The surgeon is allowed to take care of the diseases of the mouth: where, then, is he to stop? Inflammation of the throat, arising from syphilis, is referred to the surgeon—catarrhal inflammation to the physician; polypus of the nose is assigned to the surgeon—a coryza of the same part is entrusted to the care of the physician. The diseases of the bones and of the joints have been considered a part of surgery, and yet they are hardly to be called external parts. In hernia and aneurism there is an external tumor, but they are produced by the diseases of parts that are quite internal. When we come to consider the cause and nature of disease, the absurdity of the distinction becomes more apparent, and the indispensable connexion between particular parts of the frame more obvious. External diseases are often produced by internal causes, as erysipelas, nettle-rash, gout, &c.; and on the other hand, external agents produce inward disease, as in rheumatic inflammations and catarrhal affections, from exposure to cold. The eye, considered as an external part, has been entrusted to the surgeon; yet that organ is the most complicated in the body, and is subject to so great a number of diseases, that it requires a greater knowledge of the principles to be derived from general pathology and therapeutics than any other part. The eye, together with its appendages, not only contains mucous, serous, fibrous, and glandular structures, parts peculiarly liable to disease, but it suffers from gout, rheumatism, small-pox, scar-

let fever, and measles: it is affected by scrofulous and syphilitic inflammation; by cancer, fungus hæmatodes, and melanosis. If, then, an organ so complex in its structure, and subject to such numerous diseases as the eye, can be safely entrusted to the care of a surgeon, I am at a loss to know why any distinction should be made so far as disease goes between surgery and physic. It is in vain to establish distinct professorships for external and internal pathology, that surgery and physic should be taught by distinct lecturers, and in separate courses of instruction. Neither lecturers nor authors can make the distinction, and thus we find the same diseases are often considered by both; they are treated on the same general principles, and regarded in the same manner. Again, local diseases have been given to surgeons, and general ones to the physician. It really may be a matter of question, whether there be any local or general diseases, in the strict sense of the terms. When an organ of little consequence in the animal economy is slightly diseased, no sensible effect may be produced beyond the part itself; but when an important organ is considerably affected, then a great number of other parts feel its influence: hence arise general or constitutional diseases. Even in fevers we can trace the general affection to some particular organ; and the existence of fever as a general disease, independent of primary local mischief, may be made a matter of doubt. Thus, the distinction of local and general disease consists in degree, and not in kind:—it is a question of more or less. If you were to arrange diseases in one column, beginning at the most local, and ending at the most general, you would find them passing insensibly into each other, without any marked separation.

It has been recommended that Surgery should be confined to cases that require manual proceedings, or operations of some kind. This notion seems to be just worthy of that ignorance to which the unnatural separation owed its origin, and of the dark period in which it occurred.

According to such views, the distinction would depend not on the difference in the treatment of diseases, but on the accidental and often varying circumstances of the mode by which the object is to be accomplished. What shall we do with the numerous cases, such as affections of the head, gout, and rheumatism, in which changes of diet and internal treatment are necessary, in conjunction with the manual proceedings of bleeding, cupping, and leeching? What shall we do with the numerous cases, such as hernia, retention of urine, &c. which, after various internal remedies, are often followed by surgical operation? In many

cases, it is a question of degree, whether internal remedies only shall be employed, or surgical operation shall be added. If it is meant to confine surgery to operations or manual proceedings, and to a merely mechanical department of the profession, I for one must enter my strongest protest against such an arrangement. I should really feel myself degraded by exercising this kind of barber surgery. If this arrangement were carried into effect, it would not be necessary to study scientific principles. We might spare ourselves the toil and trouble of learning anatomy, physiology, and pathology, altogether; we might be contented to resign our profession into the hands of barbers, its original founders.

Historically speaking, we cannot deny that surgery originally consisted of this mechanical and subordinate part of the profession, which was practised by the permission, and under the sanction, of physicians. But surgeons have long since emancipated themselves from this bondage, and surely they will not again submit to such degrading trammels. They have cultivated with ardour and success the scientific department of the art; they can appeal to the great progress which surgery has made since the middle of the last century, and to the present state of its progression. The good opinion of the public which they have secured is not inferior to that of other scientific men. They can point in the annals of medicine to the names of men, who have been the most signal contributors to the advancement of medical science. Among these I would not omit to mention the name of the illustrious Pott. He was equally distinguished as an able practitioner and a clear and elegant writer. I must, however, confess that he has been thrown into the shade by the transcendent merits and more brilliant talents of his contemporary and rival, John Hunter. In contemplating this extraordinary character, we are at a loss to discover whether he surpassed others most in his energy or his genius. The novelty of his views and the splendour of his discoveries excite our admiration, and we are lost in astonishment when we enter his museum and view the treasures there accumulated. We can hardly believe that they could have been brought together by one individual. To this name must be added that of a kindred spirit who entered with ardour into the path traced out by his great predecessors, and followed it into new regions of knowledge. I allude to the founder of this school, Mr. Abernethy, (cheers). Fellow labourers have not been wanting in France, Germany, and Italy. It will be enough for me to allude to the names of J. L. Petit and Desault; to

Richter, Bichat, and Scarpa. The two latter have been among the most distinguished writers of modern times.

The attempt to reduce surgery to its former limits, to bring it back to the art of bandaging, bleeding, tooth-drawing, and so on, which constituted almost its entire encyclopædia in the venerable times of barber-surgery, if it could be effected would be no less injurious to the profession than to the public. The proposal now comes a century too late. In those cases in which local injury or disease exists in conjunction with a more or less general derangement, as in compound fracture with fever, in erysipelas, and in strangulated hernia, the patient requires to be attended by a person who thoroughly understands the case in all its bearings. The surgeon who only knows the local, and the physician who understands only the general treatment of cases, are but half informed, and surely deserve less confidence than one who understands both. The confidence which ignorant persons are inclined to repose in what they call a combination of talent, is fallacious, if it consists of a surgeon who knows nothing of general, and a physician who knows nothing of local management: this is not a case, like that of grammar, where two negatives make an affirmative.

Let me take this opportunity of mentioning to you, that the mere performance of an operation is often the least part of a surgeon's duty, even in cases that require it. To judge whether or not the disease admits of cure by other means, to perceive when an operation becomes advisable, to determine when it is necessary, to prepare the patient judiciously for its performance beforehand, and to manage the case well afterwards, are points of superior importance.

Do not let it be supposed that I speak lightly of operations; on the contrary, it is necessary for you to study carefully each part of your duty; but I wish to caution you against attaching too much importance to the branch of surgery that you will most seldom be called upon to exercise. It is a great mistake to suppose that a surgeon is always employed in operating, however extensive his practice. It is the boast of modern Surgery to have diminished the number of operations. I speak within limits when I assert that there are not so many operations performed now, by one-half or two-thirds, as when I first began to study the profession. This important difference to which I allude has arisen from the improved knowledge of the nature and treatment of disease. Thus, whatever view of the subject we take, the same conclusion forces itself on our minds, viz. that there is no natural distinction between physic and surgery: they are inseparably connected parts of one science and art,—the practical

principle of both having the same foundation, the different branches must employ the same means, because they have the same purpose to accomplish. Thus the great distinction turns out at last to be purely artificial—to be founded on no fixed principle—to be dependent on nothing but custom.

I have a few observations to address to you respecting the mode of studying the profession generally. Anatomy and physiology constitute the basis of all rational medicine. Doctrines which will not bear examination by this test, are merely to be regarded as idle dreams. No one would think of attempting to repair a watch or clock, or other piece of machinery, unless he understood its construction—unless he was acquainted with the nature of its movements and its connexions, and the immediate actions of the several parts: yet you find persons continually endeavouring to remedy the disorders of the human frame, not upon a slight knowledge of its construction, but in total ignorance of it, although it is a piece of mechanism more intricate than any of human contrivance.

Not only are anatomy and physiology the ground-work of medical science, but a correct knowledge of anatomy is absolutely necessary and essential to the surgeon, in the exercise of his daily duties. Without it he cannot determine the seat of the disease; he cannot understand the form and nature of the injury or accident; such as dislocations and fractures, wounds of the blood vessels, and other internal parts; nor can he proceed without great risk to the safety of the patient. You will, perhaps, be inclined to ask me how much knowledge of anatomy is necessary for a surgeon? The answer is short—just as much as he can get. Your study of anatomy must be general; no part can be excepted, unless you can point out some portion that is never liable to accident, and can never be the seat of surgical operation. In such case you can omit it. Operations may, sometimes, be performed without mischief by one ignorant of anatomy: but if any thing unexpected should occur, such an operator perhaps becomes confused, embarrassed, and frightened. In general, unless the knife be guided by anatomical knowledge, you cannot operate without great danger to the patient and great hazard to your own reputation.

I trust you will never be anxious to discover with how small a stock of scientific information you may be able to carry on the trade of your profession. Your more honourable aim will be to render yourselves correct anatomists, as a most essential step towards becoming good surgeons. The health, the limbs, the lives of your fellow-creatures, are entrusted to your care: with the greatest

skill, our utmost exertions will not do more than enable us to undertake the responsibility. What kind of a conscience can that man possess who will plunge a knife into the body of a fellow-creature without a knowledge of the parts which he divides? Who can undertake an operation without that scientific acquaintance with his art which will enable him to meet every emergency? and what must be his feelings if serious and permanent injury, or loss of life, should be the consequence of his ignorance or his rashness?

Anatomy and physiology, however, do not teach us disease. We may understand the functions of healthy structure perfectly, and yet know nothing of its morbid conditions. How then is this to be learned? Not from lectures, nor from reading—but by resorting to the book of nature. You must frequent the hospitals and the sick chamber, and you must there observe disease for yourself. Lectures and books are auxiliaries, and, under certain circumstances, very valuable ones, but they are only of secondary importance, when compared with actual observation. In order to know disease, you must see and carefully examine patients. You must watch the progress of the symptoms during life, and must explore after death the change of organization produced by disease. And here your anatomy and physiology will render you the most eminent service. How can you know the altered function, or the organic changes which are produced by disease, unless you are acquainted with the natural structure and healthy functions of the body? The wards of an hospital are the best school for studying disease; and clinical instruction, under the guidance of competent teachers, the best mode that can be adopted of acquiring information. You may be inclined to inquire whether it is not necessary to attend lectures, and read books, before you begin to see patients. I advise you to resort to nature as soon as possible. There is the same difference, in point of knowledge, between a person that has simply perused the description of a foreign country, and another who has actually visited it, as between a student who has read of disease, and one who has witnessed it. In order, however, to combine these advantages to the fullest extent, instruction must be strictly clinical, that is, disease must be pointed out and demonstrated on the patient. It is clear that clinical instruction of this kind can only be given at the time of the visit; and I have always endeavoured to do this. Those gentlemen who attended the school last winter must be aware that the lectures of Mr. Earle were of great value. He is sensible, however, they did not supersede the necessity of instruction at the bedside of the patient, which also he adopted.

Books and lectures enable the student to observe for himself, and are of great assistance in pointing out what might otherwise have escaped his notice. It does appear to me, however, that too much importance has been attached to lectures: the long habit of attending them has led to a belief that medical science can be learnt from them alone; but this is a great mistake. The most valuable part of the science rests on observation, and can only be acquired by resorting to it. It prevents the student from speculating, and keeps him to plain matters of fact. The importance of lectures, as I have said, has been over-rated, and the regulations of our public bodies, which require certificates of having attended certain courses of instruction, have tended to keep up the false impression.

Proceeding in natural order, you will attend, in the first place, to external diseases; after which you will proceed to study internal affections. In the former, the origin and progress of disease are obvious to the senses, and the evidences and principles which are derived from these sources must be applied to the more obscure affections of internal parts. Hence a physician should begin with surgery; and he who makes himself a good surgeon has done much for what is necessary to become a good physician; but do not suppose that a knowledge of surgery alone will enable you to practise physic. Your study of disease should be general; it should embrace the whole range of the subject. To the great majority of you who will have to act as general practitioners, this is obviously necessary. You will scarcely meet with two cases in a hundred which are exactly similar. Those who mean to practise surgery alone, and who, I suppose, would wish to be denominated pure surgeons, as a mark of superior dignity, would not probably be willing that, in their higher station in the profession, their portion of knowledge should be more limited than that of the general practitioner. Moreover, a learned surgeon—one who possesses a thorough acquaintance with anatomy, physiology, and pathology—will constantly be consulted under all circumstances, more particularly in cases of obscurity, difficulty, and emergency. What will be the thought of him, if he should be obliged to say that he has not studied this part, or is ignorant of that; and that a physician or an apothecary ought to be consulted? Will he allow it to be stated that he feels incompetent to manage such a case? What can he expect but to lose the confidence of those to whom his ignorance is professed, and in whose estimation he must be ranked beneath the general practitioner?

I do not advise you to trouble yourselves with a great many books at the beginning. I think the Elementary Works of Mr. Samuel

Cooper will be sufficient at first, and you may soon add to these the writings of Mr. Pott and those of Mr. Abernethy, particularly his work on the Constitutional Origin and Treatment of Local Diseases.

To those who wish to become thoroughly acquainted with the profession of Surgery, I recommend the acquirement of a knowledge of Latin, French, and German; for there are numerous sources of information in these languages.

You will understand, from the observations I have now had the honour of addressing to you, that in selecting the medical profession you have not undertaken an easy task. Indeed the study of medicine is arduous and difficult, and the most comprehensive mind and the greatest industry may find it occupy them for many years to bring up their knowledge to the present state of science. I must, however, at the same time observe, that among all the objects which engage the attention of the human mind, I know of none more agreeable than the study of medicine and surgery; while the practice of it has a most salutary moral tendency,—that of repressing selfishness, and ennobling all the social feelings. The medical profession embraces the most interesting parts of knowledge. Our first step is to learn the construction of our own frame, the mode by which we live, and move, and have our being—the means and operations by which health is interrupted and restored—by which pain and suffering are avoided.

Chemistry, natural philosophy, and natural history, are auxiliary means connected with our objects; for we are engaged in the study of nature and investigation of truth. We are not called upon to uphold doctrines or systems, nor to defend any particular set of opinions. We have no interests at variance with those of the community.

In our professional intercourse with our fellow-creatures, we are only known as the instruments of good in removing pain and sickness, the greatest of all evils; and in restoring health, the greatest of all blessings; in soothing the acute anguish which relations and friends feel for each other; and in protracting the arrival of that awful moment from which all shrink back with dread. The question of life and death often hangs on our decisions. I trust that bearing in mind these serious duties, you will eagerly embrace every opportunity of gaining that knowledge which will enable you to discharge them faithfully and efficiently. You will thus become respected members of an honourable profession, and you will enjoy in the decline of life the sweetest of all rewards—the retrospect of labour devoted to the good of others.

NEW REGULATIONS OF THE SOCIETY OF APOTHECARIES.

Regulations to be observed by Students whose attendance on Lectures commenced before January 1st, 1829.

The Court of Examiners chosen and appointed by the Master, Wardens, and Assistants of the Society of Apothecaries, of the city of London, in pursuance of a certain act of parliament, “for better regulating the practice of Apothecaries throughout England and Wales,” passed in the fifty-fifth year of the reign of his Majesty King George the Third, apprise all persons whom it may concern:

That every candidate for a certificate to practise as an apothecary, will be required to possess a competent knowledge of the Latin language, and, in compliance with the fourteenth and fifteenth sections of the said act, to produce testimonials of having served an apprenticeship of not less than five years to an apothecary, of having attained the full age of twenty-one years, and of good moral conduct.

Candidates will also be required to produce testimonials of attendance on lectures and medical practice agreeably to regulations at different times published by the Court.

Those whose attendance on lectures commenced prior to the 1st of February, 1828, will be admitted to examination after an attendance on one course of lectures on chemistry, one course of lectures on Materia Medica, two courses of lectures on Anatomy and Physiology, two courses of lectures on the Theory and Practice of Medicine, and six months physician's practice at an hospital, or nine months at a dispensary.

Those who began to attend lectures subsequently to the 1st of February, 1828, and previously to the 1st of October in the same year, will only be admitted to examination after the following course of study—viz. an attendance on one course of lectures on Chemistry, one course of lectures on Materia Medica and Botany, two courses of lectures on Anatomy and Physiology, two courses of lectures on the Theory and Practice of Medicine—to be attended subsequently to the lectures on Chemistry and Materia Medica, and to one course at least of Anatomy—and six months, at least, physician's practice at an hospital, or nine months at a dispensary; such attendance to commence subsequently to the termination of the first course of lectures on the Principles and Practice of Medicine.

Those whose attendance on lectures commenced on or after the 1st of October, 1828, and previously to the 1st of January, 1829, will be required to produce testimonials of

having attended two courses of lectures on Chemistry, two courses of lectures on Materia Medica and Botany, two courses of lectures on Anatomy and Physiology, two courses of Anatomical Demonstrations, two courses of lectures on the Theory and Practice of Medicine—to be attended subsequently to one course of lectures on Chemistry, Materia Medica, and Anatomy—and six months, at least, the physician's practice at an hospital (containing not less than sixty beds), or nine months at a dispensary: such attendance to commence subsequently to the termination of the first course of lectures on the Principles and Practice of Medicine.

Regulations to be observed by Students whose attendance on Lectures commenced since January 1st, 1829.

The Court of Examiners chosen and appointed by the Master, Wardens, and Assistants of the Society of Apothecaries, of the city of London, in pursuance of a certain act of Parliament, "for better regulating the practice of Apothecaries throughout England and Wales," passed in the fifty-fifth year of the reign of his Majesty King George the Third, apprise all persons whom it may concern:

That every candidate for a certificate to practise as an apothecary, will be required to possess a competent knowledge of the Latin language, and, in compliance with the fourteenth and fifteenth sections of the said act, to produce testimonials of having served an apprenticeship of not less than five years to an apothecary, of having attained the full age of twenty-one years, and of good moral conduct; and also testimonials of having attended two courses of lectures on Chemistry; two courses of lectures on Materia Medica, Therapeutics, and Botany; two courses of lectures on Anatomy and Physiology; two courses of Anatomical Demonstrations; two courses of lectures on the Theory and Practice of Medicine—to be attended subsequently to one course of lectures on Chemistry, Materia Medica, and Anatomy; two courses of lectures on Midwifery and the Diseases of Women and Children; and nine months, at least, the physician's practice at an hospital (containing not less than sixty beds), or twelve months at a dispensary: such attendance to commence subsequently to the termination of the first course of lectures on the Principles and Practice of Medicine.

Students are, moreover, earnestly recommended to attend Clinical Lectures, and diligently to avail themselves of instruction in Morbid Anatomy and Forensic Medicine.

The examination of the candidate will be as follows:

1. In translating grammatically parts of the Pharmacopœia Londinensis, and physicians' prescriptions; and after the 1st of

January, 1831, candidates will be required to translate portions of the following medical Latin authors—viz. Celsus de Medicinâ, or Gregory Conspectus Medicinæ Theoreticæ.

2. In Chemistry.

3. In Materia Medica and Therapeutics.

4. In Botany.

5. In Anatomy and Physiology.

6. In the Practice of Medicine.

N.B.—Physicians' pupils, who intend to present themselves for examination, must appear personally at the Beadle's office, in this Hall, and bring with them the tickets, authorizing their attendance on such practice, as the commencement thereof will be dated from the time of such personal appearance.

No testimonial of attendance on lectures on the Principles and Practice of Medicine, delivered in London, or within seven miles thereof, will render a candidate eligible for examination, unless such lectures were given, and the testimonial is signed by, a fellow, candidate, or licentiate, of the Royal College of Physicians of London.

Notice.—Every person intending to qualify himself under these regulations, to practise as an apothecary, may obtain, at the Beadle's office, at this Hall (where attendance is given every day, except Sunday, from nine until two o'clock), a printed form of certificate of all the lectures candidates are required to attend, and also of the physician's practice. The Court requests the blanks may be filled up when signed by the respective Lecturers and Physicians whose lectures or practice the student has attended.

Students are enjoined to observe, that, in future, these certificates, so filled up, will be required from candidates for examination, and that no other form of testimonials of attendance on lectures and medical practice will be admitted, except such certificates as have heretofore been received, if the same were obtained prior to the 1st of February, 1828; or such as bear the seal of a University or College, and the signature of the officer attached to such University or College whose duty it is to sign certificates of attendance on the lectures given therein.

Every person offering himself for examination must give notice in writing, to the Clerk of the Society, on or before the Monday previously to the day of examination; and must also, at the same time, deposit all the required testimonials at the office of the Beadle.

The Court will meet in the Hall every Thursday, where candidates are required to attend at half-past four o'clock.

By order of the Court,

JOHN WATSON, Sec.

London, Sept. 1, 1829.

For information relative to these regulations, medical students are referred to Mr. Watson, who may be seen at his residence,

49, Berners'-Street, between the hours of nine and ten o'clock every morning (Sunday excepted); and for information on all other subjects connected with the "act for better regulating the practice of apothecaries," application is to be made to Mr. Edmund Bacot, Clerk of the Society, who attends at the Hall every Tuesday and Thursday, from one to three o'clock.

It is expressly ordered by the Court of Examiners, that no gratuity be received by any officer from any person applying for information relative to the business of this Court.

HOSPITAL REPORTS.

ST. THOMAS'S HOSPITAL.

Case of Extensive Sloughing of the Genitals.

MARIA CARTER, æt 18, a healthy looking girl, fresh coloured, and of sanguineous temperament. Admitted into Magdalen's Ward, under Mr. Tyrrel, Sept. 9th, 1829; states that she has been leading a disorderly sort of life, drinking a good deal of spirits, especially gin, and some porter; has lately been residing in a confined district (Norfield), close to the water side. There is very extensive inflammation, attended with great swelling, about the external organs of generation. The inflammation reaches as high up, in front, as the navel, and behind as high as the small of the back; it is of livid colour, with small vesicles in different parts, containing a limpid fluid. Constitutional symptoms high; pulse quick, 112 in a minute; great pain in head and back; skin hot and dry; lips parched; tongue furred; much thirst; loss of appetite; bowels confined.

Pulv. Scam. c. Hyd. Sub. gr. xv. Pulv. Ipecac. c. gr. v. o. n. Applic. Hirud. xij. M. Pot. Carb. 6th q. horâ.

11th.—A vesicle situated over the left labium, this morning burst, and left a small sore about the size of a shilling, sloughy, and surrounded by a livid redness, which gradually degenerates into the surrounding skin. Constitutional symptoms still high.

Cont. remed.

12th.—Two other ulcers made their appearance this morning, in exactly the same manner as the one above; one situated on the right labium, the other at the entrance of the vagina.

St. Op. gr. j. o. n. Omit P. Scammon. Cont. Mist.

Lot. Liq. Calcis c. Mucil. et Op. to the wound, and Cat. Lini Lot. Spt. Vin. Rect. to the surrounding surface.

13th.—Sores, since yesterday, have spread very considerably, and now present one continuous, sloughy, irritable, surface. Constitutional symptoms very high. Pulse 112, hard and full. V. S. ad $\frac{3}{4}$ vj.

Sumat. Statim Hyd. Submur. gr. vj. M. Effervescent. frequent. Lot. Aq. Distil. c. Op. 3j. ad lîj.

14th.—Inflammation very extensive and diffused, and of livid colour. Swelling reduced considerably. Feels greatly relieved by the bleeding. Passed a better night. Bowels not yet opened.

Sumat. Stat. Calom. c. Colocynth. gr. x.

15th.—Slough has the appearance of separating in parts. Inflammation not so extensive. Constitutional symptoms very much abated. Pulse still quick, but soft, 98 in the minute. Ordered a mutton-chop to-day.

Cont. H. Efferves. et. Lot.

16th.—Sloughs have entirely separated, and the sore presents a healthy appearance, beginning to discharge a well-conditioned pus. Another small sore over the inferior part of the sacrum. Meat to be repeated.

Cont. remed.

17th.—Sores in front are looking well, discharging good pus, and are already beginning to heal. Sore on the back has begun to slough. Constitutional symptoms not so violent. Cont. remed.

18th.—Sore on the back has partially sloughed. Better in all respects.

Cont. remed.

19th.—Sores have changed since yesterday, and appear to want action. Constitutional symptoms much as yesterday. Pulse 100.

20th.—Sores more vigorous to-day. In all respects better. Cont. remed.

21st.—Passed a good night; appetite improved; not so thirsty; tongue white; bowels acted this morning from castor oil; pulse 112. Sores in front healthy and granulating.

22d.—Slough entirely separated from the wound behind. To have $\frac{3}{4}$ iv. of port wine daily.

23d.—Constitutional symptoms have returned. Pulse 112, hard and full; tongue white; bowels confined. Complains of great pain in the right side, attended with difficulty of breathing, &c.

Sumat. Stat. Cal. gr. ij. Ant. Tart. gr. $\frac{1}{4}$. Op. gr. ss. in form. Pil. Cucurb. Cruent. Hypochond. dext. ad $\frac{3}{4}$ vij. Omit the meat and wine for to-day.

24th.—Better. Difficulty of breathing and pain gone. Bowels open; tongue white;

slight thirst. Wounds in front are healing rapidly.

Sept. 28th.—The sloughing process has destroyed the entire of one labium and part of the other, as well as a considerable portion of the superficial structure of the perineum and pubes. All the wounds are closing fast, and her general health is very good.

ST. BARTHOLOMEW'S HOSPITAL.

Fatal Malignant Disease of the Mammæ.

SARAH ACRES, æt. 39, unmarried, admitted into Letwell's Ward, June 20th, under Mr. Earle, with a carcinomatous affection of both mammæ, enlargement of the glands in the left axilla, and of the glandulæ concatenatæ of both sides of the neck, and with considerable tumefaction and induration of the left arm.

She states, that in November, 1828, she first perceived the left breast to be hard and swollen. The swelling was attended with no pain, and gradually increased till January, 1829, when she observed the left arm to be swollen and painful, and then, for the first time, felt pain in the left mamma. The weather was at this time severe and frosty, and she was a good deal employed in washing linen in very cold water, with the feet constantly exposed to wet. She remained in this state, occasionally suffering more or less pain, till June, the swelling of the arm at the same time slowly increasing; when the right breast was attacked in a similar manner, and the glands in the neck and right axilla became enlarged. The pain now remitted in the left mamma, which gradually decreased in size. The symptoms presented on her admission were as follows.

Her general appearance is that of one in the enjoyment of perfect health; the right mamma is considerably enlarged and indurated, of a high red colour, with an increase of heat; the nipple is not retracted. The left breast is shrunk in size, presents a knobby and irregular feel, and the integuments covering it are of a bluish colour. Glandulæ concatenatæ, on both sides of the neck, much enlarged. Glands in both axillæ hardened and enlarged, particularly in the left, where the vein and absorbent trunks are probably compressed. Left arm, forearm, and hand, considerably swollen; the integuments stretched to the utmost in every part of the limb; the upper part of the arm of a stony hardness; acute pain in the lower part of the fore-arm and back of the hand, with loss of sensation and of power of motion in the fingers. Pain in the right mamma not very severe; catamenia irregular.

It was determined to give iodine a fair

trial in this case, and she was directed to begin taking Tinct. Iodin. ℞. three times in the day, with Ext. Conii, gr. v. The dose of the tincture was gradually increased to ℞v. and she continued taking it till July 9th, when it was thought advisable to discontinue its use internally. She had suffered more while under its influence, and felt in no respect better. A dram of the ung. hyd. potass was rubbed into the mamma for a day or two, but the friction caused great pain, and increased the heat and inflammation.

July 11.—There seemed to be a considerable degree of inflammatory action going on, and she was ordered to be bled to ʒvj. Her appearance of health has left her, and she is worn out with continued suffering. Slight scarification of the distended integuments of the arm relieve for a time the acute pains.

Liq. Op. Sed. ℞. ad xv.

27th.—The disease is proceeding rapidly to the destruction of the patient—it seems to affect the whole of the neighbouring cutaneous glandular structure; hard knotty lumps are felt beneath the integuments under the mammæ, and extend downwards towards the umbilicus. The patient suffers greatly, the pain remitting at intervals, but returning with greater severity; strength fast declining, pulse feeble. Some rest is procured from large and frequent doses of the Liq. Opii Sedat.

August 20.—The lower jaw has been kept permanently open from the enlargement of the glands in its neighbourhood. The stomach refuses to retain any thing taken by the mouth. The right breast has assumed a yellowish transparency on the surface; but the skin is not broken. There has been a little ulceration in the upper part of the arm and beneath the axilla. The poor woman has passed sleepless nights, and suffered unremitting pain during the last fortnight.

23d.—Died at 11 P.M.

Post mortem Examination.—The mammæ, when cut into, presented a peculiar structure: there was throughout a considerable degree of hardness, and the whole mass had a marbled and nodule-like appearance; here and there was observed a small cell, containing a softer substance, but there were present none of those tough fibrous bands so peculiar to genuine carcinoma. The uterus was of its natural size, but hardened in structure; in it was found a small cartilaginous tumor. The abdominal viscera all healthy. The submaxillary gland, which was considerably enlarged, had commenced to suppurate; small tumors, of the same structure as that of the mammæ, were found beneath the integuments. In the substance of the deltoid (part of which was implicated in the diseased mass) were found small tubercles. The

origin of the pectoralis major was also wholly occupied by the disease.

The entire absence of all visceral disease formed an important feature of the above case.

HOSPITAL ATTENDANCE.

To the Editor of the London Medical Gazette.

SIR,

PERMIT me to publish, in the pages of your impartial Journal, a contradiction to the statement which has recently been made in the *Lancet*, that the students of the Middlesex Hospital have not the same facility of access to the wards which is allowed in other hospitals. The statement is perfectly untrue. The physicians and surgeons of the establishment attend at the hospital every day, at a certain hour; they go through all the wards on three days in the week, and habitually visit the more serious cases once at least every day. The days on which the medical officers do not go round the house, are Sunday, the taking-in day, the out-patient day, and the operating-day. It is, of course, the duty of the pupils to be present when the physicians and surgeons make their visit; or I may state, that, from half-past eleven till three, no impediment is placed in the way of the daily attendance of students; and that, at the visit of the morning, the students are acquainted at what time in the course of the day the physician or surgeon may propose to repeat his visit to the cases, when such attendance is necessary. Among many advantages which the Middlesex Hospital presents, the following, perhaps, deserve to be enumerated. The terms of attendance are lower than at any other hospital; the cases admitted are in some measure classified; the medical wards are distinct from the surgical. Among the latter are two wards for patients with lues; one for female patients afflicted with cancer; and part of a ward expressly endowed by one governor (the late Mr. Stafford) for the relief of male patients labouring under the same disease. The hospital, which is as large as that to which Mr. John Hunter and Dr. Baillie were attached (and which itself claims the honour of having had Dr. Wm. Hunter and Sir Henry Hallford among its medical officers), is placed in a remarkably airy and healthy situation; and being well built and ventilated, has always been free from those periodical visitations of erysipelas and hospital gangrene, to which many other establishments of the same kind are liable. I am happy, too, to have to state to you, that it is in contemplation to enlarge the present building, by constructing an additional wing upon part of the large space of ground connected with the hospital. I am

sure, Mr. Editor, that, after the cool abuse with which the *Lancet* has honoured us, you will not refuse to insert this vindication of my old Hospital.

I have the advantage of being, Sir,
Your constant reader,

JOHN MIDDLESEX.

Sept. 30.

NOTE FROM BARON HEURTELOUP.

To the Editor of the London Medical Gazette.

SIR,

HAVING had communicated to me the substance of the following extract from the letter of one of your correspondents, who says, speaking of my instruments, "M. Civiale and myself have had those instruments several times in our possession;" I beg to say, that it is probable your correspondent has been mistaken as to the identity of the instruments, from the following circumstances. Although I have given, in England and France, about thirty demonstrations of them, in public and private, it does not appear that those gentlemen obtained their knowledge at any of these, from the circumstance not being mentioned, and from the expression that they had them in their possession.

I have always kept my instruments at home; and no one can have seen them, unless by obtaining the sight of them from the persons to whom they have been entrusted in confidence. It is not likely that M. Civiale, or your correspondent, should have made so improper a request. The account given by both gentlemen of those instruments, bears evidence of the little acquaintance they have with them.

Had it been really my instruments which M. Civiale and your correspondent had seen, it is not likely that they would have given an opinion of them so totally at variance with that of the Institute of France, and the circumstance of its having honoured me with the great prize of Surgery on account of them.

I send you an account of the cases of MM. Desangiers, Riviere, Courtois, Neurohr, Delamontagne, and Bocquet (not Rochet), which will, I trust, prove an answer to your correspondent, at the same time that they are merely scientific notices*.

I shall also soon have the honour of sending you my own observations on the case of Mr. Woltre, which will be a scientific (not a polemical) answer to your correspondent.

I have the honour to be, Sir,

Your obedient humble servant,

HEURTELOUP, D.M.P.

* We have been compelled to postpone these cases till another Number.—E. G.

LECTURES ON SURGERY,
Delivered at St. Bartholomew's Hospital,
BY WILLIAM LAWRENCE, F.R.S.

LECTURE II.—Oct. 2.
On the Nature and Divisions of Disease.

GENTLEMEN,

It is the object of medicine to ascertain the nature and seat of disease, in order to discover the proper mode of treatment. If we understood in each instance what organs were the seat of disease, and how they were affected, there would be very little difficulty as to the subject of treatment. We should then be able to give an appropriate name to each disease; and we should also be able to arrange them according to natural events—that is, we might establish a rational nosology, or an arranged catalogue of diseases.

Now it happens unfortunately for us, that in a great many instances we are unable to determine the nature of disease; and in not a few instances, we cannot even state the exact seat of it. Hence you will not be surprised at finding that the names of diseases are in many instances calculated to mislead, and that those catalogues of diseases which are called nosology, are really worse than useless. The difficulties, however, to which I allude, are not in reality experienced so much in that part of the subject which is the immediate object of our attention—viz. the surgical department. They are more forcibly felt in the cases of affection of internal organs, where the means of investigation are not so numerous, and where there is greater difficulty in all parts of the inquiry. Most persons imagine that they understand very well the meaning of health and disease, yet it is not altogether easy to give the definition of these two states to complete satisfaction. Health and disease have been said to be two opposite states of the body, and certainly under particular circumstances we may admit that this representation is correct. For example, a person in a state of full health may be considered nearly in an opposite condi-

tion to that of a person in the last stage of fever. However, health and disease are not to be regarded simply as two states that can be thus compared, for under each of these terms is included a great variety of conditions, which differ materially from each other. On one side, a state of health passes, by an insensible gradation, into a state of disease; and on the other side, disease in the same way is shaded (if I may use the expression) gradually into health; so that when we come to survey those conditions which approach to each other on their boundaries, we often find a considerable difficulty in determining what is health and what is disease.

The human body consists of a great number of organs, each of them executing its own particular function, and all of them concurring in the general purposes of organization, which are to preserve life, to keep up the relation which connects the individual with the surrounding world, and to continue the species. When the structure of organization is perfect, and when the functions are regularly executed, the individual is said to be well, or in a state of health: the notion of health, therefore, combines these two circumstances, perfect structure and perfect functions. The word natural, as applied to the healthy structure, is rather equivocal, for we must admit that disease is a part of nature. The French and the Germans use the word normal, in order to describe what we call a healthy structure. This term is about equivalent to the English epithet, regular; thus the normal, or healthful structure, and regular execution of functions, would be opposed to disease, or the irregular functions of the body. Such is the general idea that we must form of the two states of health and disease.

Disease has been defined an improper or irregular execution of one or more functions of the body. This definition, however, seems to me peculiarly defective, for in fact it omits a circumstance which is of primary importance in the consideration of disease, namely, the state of the organs. The definition,

however, is correct as far as it goes; for, wherever we see an irregular execution of any function, we may safely conclude that disease exists; but we may have disease, and that of a very unequivocal kind, existing in the body, without any observable deviation from the natural state of the functions. Now warts and corns are considered to be a disease, and at all events, steatomatous tumors are diseases; yet these may arise, and they may acquire a considerable size, without the individual being aware of their existence; and even when they have arrived at a considerable magnitude, occasionally they do not disturb any function of the body, and are perhaps only inconvenient by their bulk. But suppose we take the case of even so formidable a disease as that of cancer affecting the female breast. Cancer will commence with induration and swelling of the mammary glands; and this will take place so insensibly as to attain a considerable size before the female is aware that any change has occurred, and, in fact, the tumor is discovered accidentally.

You will see, therefore, from these various circumstances, that the definition of disease, if it turn on the state of the functions, is by no means satisfactory; we must at all events regard, as of principal importance, the state of the organs of the body. We may call disease a deviation from the normal, regular, or healthy state of any solid or fluid of the body, or of any function. These various circumstances may be exemplified in the case of the stomach. The stomach may be in a state of inflammation, or may be in a state of cancer; and in both cases there is a manifest change in the structure of the organ—in the former a temporary change, in the latter a permanent change. In the case of heartburn there is an acid secretion in the stomach, and in yellow fever there is a morbid secretion, evinced by the ejecting from the stomach of substances like coffee-grounds, which are called black vomit. Here you have fluids affected by the stomach. Again, in nausea, sickness, and indigestion, you have the functions of the stomach impaired, and the organ deficient in the office which it has to perform. So that in the case of the stomach you see exemplified the three kinds of alteration which are mentioned as constituting disease—a deviation from the natural state, so far as the solid goes, or a deviation in the state of fluid secretion, or an alteration in the condition of the functions.

You will perhaps be inclined to think that the three circumstances which are combined in the definition now mentioned, might properly be reduced to one. You will be inclined to ask whether the functions of the organs can be disturbed if the structure of the organ remains entire? You will be inclined to ask whether the fluids of any part can be altered if the solid remains in a natu-

ral state? And these questions are very reasonable and proper. If a change of the functions implies an alteration in the state of the organs, and if a change in the state of the fluids involve an alteration in the state of the solids, then the definition of disease would merely embrace the alteration that may be produced in the organ itself. I can entertain no doubt, for my own part, that if our knowledge of diseases were perfect, we should be able to trace in every instance the alteration of the functions, to the alteration in the state of the organs. But unfortunately for us, our knowledge of disease is not yet perfect. In many cases we see a change in the functions of a part, when we cannot ascertain exactly what is the condition of the organ; more particularly in the case of internal disease. In many instances there are altered functions, or manifest symptoms of disease, and we are unable to say what organ these symptoms should be referred to. Therefore, in our present imperfect state of knowledge, we must admit that alterations in the functions, or changes in the state of the fluids of the body, is disease, without meaning to assert that this change does take place independently of alteration in the condition of the organs themselves. We admit such a change in the function to be disease, because we do not happen to be able to say precisely what is the condition of the organ to which the function belongs; but we do not assert that the organ continues unaltered in a state of disease.

In considering the changes which the body may undergo, we must bear in mind that they differ much in degree. There may be a change in the state of an organ of such a kind that the alteration may be visible after death, when we come to examine the part; and there may be a change that may merely affect the living condition of the frame, and which leaves no traces distinguishable after death. I do not mean to represent to you (for I do not believe it myself) that the functions of an organ can be altered, while the organ itself remains in a perfectly healthy and regular state; for, in fact, what are functions of the body? Merely the results of the exercise of the organs. The functions are the organs in a state of active exertion: the functions and the organs, with respect to each other, are cause and effect. A perfect state of the functions implies a perfect state of the organs; and an imperfect or irregular state of the functions supposes a disordered state of the organs. To say that the functions were disordered without any change in the organs, would be to say that an effect had taken place without a cause.

We come back, then, to the point just mentioned, viz. that in considering the changes that may take place in the organs of the body, we must divide them, first, into those serious changes which are visible by examination after death; and, secondly, into

those slighter changes which affect merely the living condition of the parts, and are not ascertainable after death. The living condition of every organ which is necessary for the regular execution of the functions, comprises not only the state of the structure which we are capable of ascertaining by examination after death, but also all the various internal movements which belong to a part in a healthy living condition; it likewise includes a healthy state of the fluids, and of that influence which connects the part with the nervous system, and in many cases sympathetically with other organs of the body. Now nearly the whole of the slighter changes elude our observation, for we have no means of ascertaining them; therefore in a great many instances we cannot say whether a certain organ in a living state is in a condition fitted to exercise its functions properly or not. Under certain diseases we can see how the organ is affected, by the changes that I have just alluded to: we can observe how the function is influenced by this kind of alteration. The function of the brain, for example, will be suspended, sensation and voluntary motion will be put a stop to, when the action of the heart is suddenly stopped, as in syncope; or when the function of the lungs is arrested, as in the case of suffocation. The function of the brain, under these circumstances, is stopped; and yet, if we examine the brain after death, we do not find any change in its structure. But what happens if the heart stops its action? Why, no more blood is sent to the brain—it no longer continues to furnish that supply of blood which is one of the necessary conditions to the healthy influence of the brain over the other parts of the body. In consequence of the supply of blood being thus suspended when the heart stops its action, the brain no longer exercises its influence, and sensation and volition are at an end. When the functions of the lungs are impeded, the blood no longer undergoes that change from venous to arterial, which is of so much importance to keep up the functions of all parts of the body. The effect of the change is speedily felt by the brain: whenever the blood sent to it becomes of a dark colour instead of being scarlet, its function is at an end. In both cases we see that a certain change is produced in the living condition of the brain, which suspends its influence over the rest of the body, although there is no alteration in the structure that is ascertainable after death. When, therefore, we speak of diseases being functional, we merely mean to express that they are not accomplished by any change in the state of the organs that is ascertainable by dissection; and we use the word functional in contra-distinction to organic, which denotes visible changes in the organs of the body, ascertainable by dissection after death. That is the sense in which these terms are employed.

Now it must be observable, that the words functional and organic, as applied to diseases, are often used rather loosely, and by no means in the strict sense now mentioned. When the brain can be said, strictly speaking, to be under organic disease, it implies changes having taken place in the organ that can be detected after death. But such is not the sense in which the term is commonly employed by the modern writers of this country; in fact, they range in general, under organic influence, alterations of a temporary kind—for instance, that of inflammation. A serious change certainly takes place under the condition of inflammation; but the change is a transitory one, and may leave the organ in a state of uninterrupted action. Therefore the word organic does not generally comprehend this state, but is used to denote those more serious alterations in the structure of the body which are permanent—which do not admit of change—such as that which takes place in cancer, ossification, tubercles, and changes of that kind. The same looseness of language in this respect is observable in the writers of other countries: thus Richerand, in a popular work called *Nosographie Chirurgicale*, which has been published in France, divides the diseases of all parts of the body into three classes—physical injuries, 1. *Dérangemens physiques*—organic changes, 2. *Altérations organiques*—vital changes, 3. *Lésions vitales*. Now, under the latter head, he includes inflammation: The difference between functional and organic diseases has sometimes been marked in our own language by the terms disorder and disease; but this use of these two terms is neither sanctioned by their common acceptation, nor indeed by their etymological signification, for in all common language disorder and disease are synonymous—they are used without any distinction, and if we come to enquire what is their meaning, they seem to be nearly the same. What is disease? It is an interruption of ease—it is a change in the feeling. What is disorder? An interruption of order—it is an interruption of the regular execution of the functions of the body.

The examination which we make after death is not a satisfactory criterion of the change which may take place in the state of an organ during life. There are certain changes of an obvious and important kind which seem to take place during life, and of which we find no trace after death. In the case of erysipelas, there is a determination of blood to a certain part of the skin; there is a considerable distention of the blood-vessels; there is an increased redness of the part. But all these appearances are lost when we examine the part after death. If, therefore, we referred to the state of the skin as it is found after death in the case of erysipelas, we should say that the skin had not undergone a change, and yet in the liv-

ing state we observe a manifest change. In the case of inflammation of the eye, there is an external redness visible, but this is lost after death. We are not, therefore, to conclude, because we can discern no change in the state of the part after death, that no change took place during life. We are not now considering whether a function can be diseased without a change in the state of the organs: our principal point is to ascertain whether there was a change in the living condition. The examination, therefore, after death, is an uncertain criterion, and is not decisive of the point in question. Again, before we can determine that no change has taken place in the organs, our examination after death must be a very accurate one, and the examination must be performed with the aid of a very accurate and complete knowledge of the healthy normal or regular state of the part; for, without the person has that knowledge, it is impossible to determine whether changes have not taken place, and been overlooked. Thus, we find, that in proportion as pathological investigations after death have been conducted with greater accuracy, the number of diseases supposed to be functional has been diminished. Fevers have been supposed to arise from the diseased functions of the brain, but the more accurate pathological inquirers of modern times have found out that a great many organs of the body are considerably and obviously diseased in the case of fevers. Thus, it is found, that this complaint, instead of being a functional disorder, belongs to organic diseases. The divisions, then, of disease into functional and organic, according to the view that we now take, must be regarded rather as a difference in degree, than as a difference in their essential nature. In the case of the diseases called functional, the changes that take place in the organs may be of the slightest degree, which leaves little or no trace after death. In diseases called organic, the alterations in the natural condition of the parts are of more considerable kind, and they leave behind them changes visible after death. I can by no means agree in opinion with those who regard functional disease simply as affections of the functions, or vital property, without reference to the organs by which they are exercised; and yet this is the sense in which the terms are very frequently used. How can we conceive that functions, or vital properties of parts, can be altered, if the structure of those parts remains in a normal, regular, healthy state? What would any of you think, if you were to take your watch to a maker, and he, looking at it, were to tell you there were no alteration whatever; no defect in the construction or adjustment of any part of the watch, but that the movement was affected? You would think it a strange opinion to receive, that

the watch would not go well if all the parts were actually in their perfect state. If, on the contrary, the watchmaker were to tell you that, in consequence of the watch not going well, there must be a change in some of its parts, but that he was not able to discover it, he would speak rationally. And that is the circumstance in which medical men find themselves when, in derangements of the body, they examine the organs, and do not observe the state on which the defect depends. They ought to make investigation more perfect, (for the art is not arrived at the perfection it is susceptible of,) and not to assert that the functions and vital powers are in a disordered state, while the organs remain in their natural healthy condition.

Now this is not a point of merely speculative importance, but one of considerable practical use: for those persons that believe in the existence of functional vital disease direct their treatment according to the views they entertain of these disorders. Their object is to remedy the imperfection of the function; to excite the vital properties which seem to be deficient in energy; to rouse those that appear to be dormant; and their treatment, in many respects, is calculated rather to aggravate disease than to remove it. Persons who entertain views of this kind consider paralytic affections to be merely the loss of nervous power in the part affected. If the patient is unable to move the limbs of one side of the body, they say that the nervous power is deficient in those limbs; that it is necessary to rouse them, to stimulate them, to raise them up to their proper degree. They treat paralysed limbs by stimulants of all kinds. If the affection be local, they administer local stimulants, to arouse the nervous action. They institute a plan of local treatment by stimulants in cases in which a more accurate pathological research proves that the disease exists in the brain, and that it consists, perhaps, in an increased determination of blood to the head, in a serous effusion, or in various changes of structure, all of which are, in fact, aggravated by this stimulant treatment. We have examples of a similar kind of erroneous treatment, proceeding on this erroneous theory, in affections of the eyes. When the nervous structure of the eye is affected, as those parts are so deeply seated as not to come under observation externally, we cannot actually see them, but know that the retina, or optic nerve, is diseased. The patient's sight is dim; he says it is weak, and that it wants to be strengthened. And medical men take up the same notion as the patient. They fancy that the powers of the nerve want exciting, and that it is necessary to use means to strengthen the vital properties of the patient. They treat the patient with stimulatives, in order to raise this supposed

deficiency of vital property or function, and all the while the affection of the nerve is one of an inflammatory character, which is either more or less chronic.

From the want of observation in the cases of fever has arisen the notion of debility, or suppressed energy or diminished energy, of vital functions, and the stimulating treatment, as pursued in consequence of this view. The same may be said with respect to the functions of the chylipoietic viscera in indigestion, where all kinds of tonics and stimulants are poured into the stomach in order to raise what are supposed to be deficiencies in the vital energy of that part.

It has been remarked, also, that the fluids cannot in any case be altered in their properties, except through the medium of some change in the solid parts of the body. Now the fate of the fluid parts of the body, in reference to disease, has been rather singular: for, at one period of medicine, the explanation of all disease turned literally on the changes that were supposed to take place in their composition; and, at a subsequent time, all share in the explanation of phenomena has been denied them. In the early period of the medical art, when anatomy and physiology were unknown, the enumeration of the fluids of the body was a kind of imaginary one; and these imaginary fluids were supposed to be capable of derangement in a variety of ways, which were analogous to the changes that certain fluids would undergo out of the body. These fluids of the body were supposed to be susceptible of numerous chemical and mechanical changes: they were supposed to be capable of separating into what were called particles, which were thick or thin—and so forth. All parts of disease were explained on the supposition of imaginary changes in the fluids of the body, and the means of treatment were directed to remedy these supposed alterations. When anatomy and physiology came to be cultivated—when the changes that took place in disease came to be investigated by examinations after death—of course all these notions were put an end to; and from that time the very term of humoral pathology, which includes this kind of explanation of disease, has become a sort of by-word of contempt. It has been considered that the fluids of the body are quite foreign to all explanations of disease. Perhaps, however, we are going too far in denying the possibility of all changes in the fluids, and denying to them all share in the production of the phenomena of disease. You will consider that all the supplies of new materials enter the body in a fluid state, and that all new materials pass into the blood. When you consider the various kinds and various qualities of new material that enter the blood in this way, you cannot help supposing that there must be a considerable variation both in the

quality and composition of the blood; and you cannot help admitting that these variations may have considerable power over the organs of the body, in producing changes in them. Only compare, for an instant, an individual in a state of health with a scorbutic sailor, and you will find an essential difference in the nature and composition of the blood; differences which may be capable of explaining some of the morbid conditions which we witness. The secretions of the body probably depend, in a great measure, on the state of the secreting organs; but we cannot help observing that they must also depend, in part, on the nature of the matter on which the organ acts. When we see various states of urine, which we can trace to variations in the quality or kind of food that comes into the body, we cannot help allowing that the state of the fluids deserves consideration in estimating disease; and we cannot help recollecting, that although those doctrines which constituted the humoral pathology were most unfounded, yet that this does not form the least reason for excluding fluids from consideration in viewing the phenomena of disease. Now it is true that the means of investigation, so far as the fluids of the body go, have been cultivated much of late years, and various views have arisen in relation to them; but, generally speaking, I do not know that, in the present state of our knowledge, we can derive any practical information as to the state of disease and the means of removing it from ascertaining the condition of the fluids; still we must observe that this is no reason why we should not, in consequence of farther investigation, derive considerable assistance from that source.

In concluding these remarks, I may certainly express to you my opinion, that, if disease were perfectly understood, we should be able, in each instance, to refer it to some changes in the state of some organ or organs of the body; and, consequently, the changes that take place in the functions would constitute merely external signs or symptoms of disease. I must observe to you, however, as I have already intimated, that the state of medical knowledge, so far as we have hitherto arrived at the point, is so imperfect that, in many cases, even in diseases of consequence, and those too of frequent occurrence, we are unable to assign the organ that is disturbed, and from which the phenomena flow. Thus, for example, in common fevers, the profession are by no means agreed as to the particular organ which is the primary seat of disease in these affections. In cases of intermittent fevers, which are diseases of very common occurrence, we should be totally at a loss to assign the organ which is in fault: we cannot tell what is the seat of disease in that affection. The state, therefore,

of medical science, will not allow in our day of what we may suppose will be done when pathological investigation is more advanced; that is, of reverting, in each case, from the altered functions or symptoms, to the particular alteration of some specified organ. In cases of internal disease, the changes which we are able to discern frequently cannot be referred to any assignable change in the state of any internal part, and we are obliged to name diseases after certain external and visible signs; and yet we are sensible that the names which are given are applied rather to the symptoms than to the disease. Thus, in one case, we see the urine is passed with difficulty; and when it is in the state in question we call it dysuria. It is only for want of better information that we take the term from the external disease. In another instance, we see the urine is tinged with blood, and we cannot tell what quarter the blood has come from. Hence dysuria and hæmaturia are only symptoms of a disease which, in a more advanced state of knowledge, we ought to refer to some specific organ. Dyspnoea—what is the meaning of that? Difficulty of breathing. But this is not the disease; the difficulty of breathing may be produced by various changes of various parts. We must bear in mind, then, that these are only the names of symptoms, and we must endeavour, as far as we can, to investigate the difference in the organic changes that give rise to the symptoms; nor ought we to be satisfied till we have found what the organ is that is really affected.

All organs of the body may be *primarily* affected; that is, they may be affected by causes acting immediately upon them: and all the organs may be affected *secondarily*; that is, in consequence of disease previously existing in some other organ. If boiling water be poured upon the skin, inflammation of the skin is produced;—if a wound is inflicted on the skin, inflammation will follow;—these are primary affections of the skin. If a person takes certain sorts of food into the stomach, as for instance, shell-fish, or if his stomach becomes disturbed in some particular way, he will have an attack of nettle-rash or erysipelas. In the one case the skin is affected primarily, that is, by a cause applied to it; in the other case the skin is affected secondarily, in consequence of a disorder or a disturbance produced in an internal organ, the stomach. If a person has a fulness of blood in his head, or if he employ his mind intently upon some subject, he may get giddiness, or other symptoms of disorder, in the head. So also he may get the same kind of symptoms if his stomach be overloaded with food, or his bowels should be costive. Here you have primary and secondary affections of the head. If the stomachic power be disordered, a person will be rendered sick by

the approach of certain substances or certain kinds of food: and serious injury of the head will also produce sickness. Here we have primary and secondary diseases of the stomach. Primary disease is called *idiopathic*, and secondary disease is called *symptomatic*. Idiopathic, or primary disease, is the disease or disturbance produced by a cause immediately acting upon the part; symptomatic, or secondary disease, is the disease of any part dependant on the existence of disease in some other organ of the body.

I fancy there ought to be no difficulty in conceding these principles; namely, that all the organs of the body may be primarily diseased, and that each kind of organ will admit of being disturbed in the execution of those functions which naturally belong to it. Thus the lungs, or organs of respiration, may undergo disturbance in the execution of their functions; the stomach and alimentary canal may be disordered in their functions—and so forth. When we come to examine the modes in which the various functions of the body are exercised, we can easily see the manner in which the various organs may be disturbed from the causes applied to them in the course of their natural operations. Yet, when persons have taken up certain notions respecting the preponderating importance of this or that part, they have sometimes been inclined to refer all diseases to the primary disturbance of some one or other part of the body. Thus, one observer has attached great importance to the liver, and has fancied that disease in that organ is the source of almost all diseases in the body. Another observer may attach great importance to the diseases of other parts of the chylopoietic system, as the stomach and bowels, and digestive organs generally. This has been the case of late years, particularly in the metropolis of a neighbouring country, where a physician of great eminence has, I believe, held the opinion that almost all diseases of the body originate in the part of the frame before referred to, viz. the stomach and alimentary canal. I should regard all these views as partial and erroneous, and I should have no hesitation in admitting, what I have already stated, that all parts of the body may be primarily diseased, and, no doubt, in admitting that all parts may also be secondarily diseased. We may admit further, that in proportion to the importance of any particular set of organs in the body, will be the influence which they have in exciting disease in other parts. No doubt, in this point of view, the parts that are concerned in digestion—the stomach and the alimentary canal, and the subsidiary organs—will have a greater influence in exciting disturbance in other parts of the body than many other organs. But we must not look to them as the seat of all

other diseases. We find clearly that the brain, the centre of the nervous system, may be diseased, without a disease existing in those parts, by a cause that is applied solely to it. Intenseness of application, mental exertion and anxiety, and a variety of causes that are capable of acting on the brain alone, may disturb it, although the stomach and alimentary canal generally shall be in a healthy state.

Now in most diseases you find a combination of symptoms that are referable to both these heads—that is, you find certain symptoms that arise from the disturbance of the affected organ; and you find other symptoms, that arise from the influence the organ may have over other parts of the body. Thus you have certain primary symptoms, and certain secondary, or sympathetic symptoms. When we say one part sympathizes with another, we merely denote the fact that the affections are coincident, and take place at the same time. What is the meaning of the word sympathy? It merely means *suffering with*. If, in an affection of the head, the stomach is deranged, and we say the stomach sympathizes with the head, we merely express that the stomach suffers in conjunction with the head, or at the same time as the head: sympathy merely means that. When we see a person in a state of anxiety, or distress, or pain, or suffering, and we feel an unpleasant emotion ourselves, we sympathize or suffer with the individual;—in the same way one organ suffers with or sympathizes with another. In the animal economy the word merely denotes the circumstance that the affection of one organ takes place in conjunction with another. It does not explain the fact. When we come to inquire how this is produced, various explanations may be given, according to the various causes. With regard to nervous sympathy—the nerves are distributed over all parts of the body, and particularly the nerves in conjunction with those common centres to which I have before referred. The brain, and the spinal cord, afford easy means to understand how it is that various organs are combined together in their morbid as well as in their natural functions. The sympathetic effects of one organ upon another differ materially under various circumstances. We find that the sympathetic effect is more powerful in proportion as the organ primarily affected is of greater importance in the animal economy; and the affection of the organ is of greater consequence in proportion as the individual in whom the affection takes place is more irritable, or of a more excitable system.

A LECTURE

ON THE

CONDUCT AND DUTIES OF THE
MEDICAL PRACTITIONER,

Delivered at the Theatre, Great Windmill-Street,
Oct. 5,

By B. C. BRODIE, F.R.S.

[MR. BRODIE commenced his Surgical Course on Monday evening, when he was received by a very numerous class with the warmest testimonies of cordiality and respect. On this occasion we present our readers with his introductory lecture, and hope in the present volume to give that portion of the course which treats of Calculous Disorders, so as to complete the valuable set of papers on the diseases of the urinary organs which was commenced in our first volume.]

GENTLEMEN,

You are assembled in this metropolis for the purpose of obtaining that knowledge which is to render you qualified to exercise the profession of the healing art; and I undertake, in the ensuing course of lectures, to give you some instructions relative to that department of it which we distinguish by the appellation of surgery. I say that I undertake to give you *some* instructions—for let it be observed, that it is impossible, solely through the medium of lectures, to acquire such exact and various information respecting either medicine or surgery, as, superseding other methods of study, will make you competent at once to enter into society as candidates for practice. I shall endeavour to point out to your observation the grand distinctions of surgical diseases, and the principles on which your treatment of them is to be conducted. But even of what I shall have occasion to advance, you will find that many things will neither be well comprehended, nor accurately remembered, unless you combine your attendance on these lectures with other means of obtaining knowledge—unless you compare the histories which I may give you of disease with what you actually see at present, or may have seen formerly, in the wards of an hospital, or in other places. As to the more minute distinctions of disease, and the nicer rules of practice, for a knowledge of these each individual must be indebted altogether to himself, learning them, not from books or lectures, but at the bed-side of patients; and others cannot assist him in this part of his labours further than by shewing in what manner he may prosecute his inquiries with the greatest possible advantage.

The animal body may be considered as existing in two different conditions. In the first, its natural structure is complete, and the functions of its various organs are duly and regularly performed; while in the other,

either its natural structure is altered, and its functions are in consequence impaired, or its functions are deranged, independently of any alteration of structure. It is this last condition which constitutes disease; and it is the correcting of the various aberrations which occur from a state of health, which forms the ultimate object of attention to the physician and surgeon. But the body in its perfect state, with its organization complete, and its functions regular, is the only standard by which we can judge of these aberrations; and the study of anatomy and physiology is, therefore, the first and most important step towards acquiring a knowledge either of medicine or surgery. I need not occupy your time, nor ought I to insult your understandings, by producing arguments in favour of so plain a proposition; and in these times, when knowledge has become so universally diffused, and the opportunities of acquiring it are so extensive, I need not caution you against the example of those whose indolence or conceit may have misled them into the belief that they could be enabled honourably to pursue the profession either of medicine or surgery, without having first made themselves acquainted with the other preliminary sciences. Let the student in the dissecting-room, with the scalpel in his hand, observe the form, the general appearance, and relative situation of the organs, which enter into the construction of the human body; let him then engage in a more minute analysis, and unravel the various textures of which these organs are composed; let him avail himself of what is taught in lectures and books, and of his own powers of observation and reflection, so as to understand the offices which severally are allotted to them, and the relations which they bear to each other; and let him use the knowledge which is thus acquired as the only firm foundation on which he may erect the superstructure of pathological and surgical science.

It is, however, chiefly to other objects that I wish to direct your attention in the present introductory lecture. In the outset of your studies, it is natural that you should inquire what are the qualities of mind which will best enable you to succeed in the career which you have begun, and which you should, therefore, especially cultivate? What is the peculiar nature of the duties which you owe to society and to yourselves? What are the advantages and disadvantages of the profession in which you are engaged? and how are you to pursue it so as to be enabled to pass through life with comfort, and credit, and satisfaction?

Gentlemen, there is no profession in which so much is entrusted to the honour and integrity of the individual as in ours; and, therefore, there are no persons who are called upon to be more scrupulous and exact

observers of all the rules of moral discipline than ourselves. How little of what passes between the medical practitioner and his patient is known to any one but themselves! How little can the patient judge, in the majority of cases, of the correctness and propriety of what is said and done! Received into the bosom of private families—becoming acquainted with circumstances of domestic history, which are not intended for the world—seeing, day after day, human nature humbled in affliction—children attending their sick parents—parents trembling for their children, watching for every gleam of hope which may shine in upon them, and rendered miserable even by a look or thoughtless word—credulous from anxiety; how much opportunity is there for us to cultivate our better and more virtuous inclinations! And on the other hand, how easy is it for a selfish and unprincipled person, availing himself of his peculiar situation, to convert the anxieties, the hopes, and fears, and the easy faith of his patients, their relatives, and friends, to some base purpose of private lucre and advantage! But shame be to those who betray the confidence which is reposed in them as medical practitioners! These are traitors to our common cause: the fair fame of our profession is the property of us all, and every blot upon it is an injury to each of us individually, inasmuch as it tends to lessen the estimation in which we are held, and to give us a lower place in that society of which we constitute a part.

While, however, we thus attend to the duties which we owe to society at large, let us not lose sight of those which we also owe to the smaller community of our own profession. Within certain limits, each individual among us has it in his power to influence the opinion of the public with respect to the character and conduct of his professional brethren; and occasions will not be wanting which will offer some inducement to a shortsighted, ill-disposed, or self-sufficient person, to endeavour to obtain credit which he does not in reality deserve, at the expense of another practitioner. Candour and generosity belong to youth, and I am willing to believe that there is no one among those whom I now address who does not feel that he would be degraded and disgraced if he were to stoop to such mean and dishonourable methods of self-advancement. Gentlemen, may these sentiments, which nature and education have implanted in your hearts, remain with you in your maturer years! May they never be allowed to perish from neglect, during the sunshine of professional success! May you continue to cultivate them even under the shade of professional disappointment! That simple but comprehensive principle of Christian morality, which inculcates that you should do unto others as you would they should do unto

you, is applicable to our peculiar pursuits as much as to those of common life. And here, as on most other occasions, fortunately for the weakness of human nature, those whose views are not confined to the present moment, but who look to the ultimate result, will discover that propriety and expediency go hand in hand. Rarely does it happen that he who has used his best endeavours to improve himself in skill and knowledge—who has been honourable in his dealings with the public, and just to his own profession—has reason to complain, at the end of his career, that he has failed in his undertakings. The friendship of his competitors, and the respect of society at large, attend him in the decline of life, and serve to illuminate that which would be otherwise the darkest period of his wordly existence.

Gentlemen, if there were nothing to occupy our attention beyond the study of morbid actions and changes of structure, and the application of remedies for their relief, the practice of our profession would be comparatively simple. But in those beings on whom our art is exercised, we find, super-added to the animal frame, the percipient and thinking mind, endowed with feelings, passions, and prejudices; and in many instances having the judgment weakened, feelings rendered more acute, and prejudices aggravated, by the influence of corporeal disease; by long confinement; by sleepless nights and tedious days; by anxiety and pain. It is to the advantage of others, as well as necessary to our own satisfaction and comfort, that, while we study the functions of the body, we should also pay attention to the movements of the mind. We should regard our patients as influenced by moral as well as by physical causes, and requiring different treatment, according to the peculiarities of their mental constitution, and the peculiar circumstances in which they are placed. But who can control the minds of others who has not first learned to regulate his own?

Γνωθὶ σεαυτὸν — know thyself! This maxim, which was inscribed over the portico of the temple of Apollo, as an admonition from the Deity to all mankind, may, with good reason, be especially addressed to the members of the medical profession.

It would undoubtedly be remarkable, if we, who are inured to scenes of woe, and engaged in the daily contemplation of human nature, labouring under such a variety of afflictions, were to be affected by the sufferings which we witness in the same degree as an ordinary observer; neither is it desirable that it should be so. The heart would break; the head and hands would be unfitted for the duties which they are required to execute; if, as we advance in life, retaining the keen sensibilities belonging to our earlier

years, we were still to become faint, and sicken at the sight of a tedious and painful operation, or turn with disgust from a patient who is sinking under the influence of some incurable and loathsome malady. Let us not, however, fall into the opposite extreme of insensibility to the miseries of others. Surely there is nothing in the nature of our pursuits which should operate upon our moral character so as to annihilate our better and kinder feelings; and if there were, we ought to endeavour to counteract such a prejudicial influence. I do not hesitate to assert that the person who can look with indifference at the various calamities which are connected with disease, is not one who can deserve the confidence which ought to be reposed in a medical practitioner. Mere upright principle, indispensable as it is in one of our profession, is insufficient in itself; some gentler qualities are necessary to give full effect to the most honorable and correct intentions; and without them that degree of anxiety for our patient's welfare cannot exist which leads us to watch over every change that may take place in a dangerous complaint, and to attend to the minute but important details of medical and surgical treatment.

There is nothing which distinguishes the individual who has enjoyed the advantages of education from the uncivilized man more than this circumstance, that the latter is the slave of his passions, which are almost the sole motives of his conduct; while in the former these are, or are expected to be, in a very great degree, subjected to the dominion of the intellect. There is no person to whom this power of self-command is more essential than it is to the medical practitioner. The occasions which call for the exercise of this faculty are of daily, I may say of hourly, occurrence. The individual who is in a state of constant torture, or whose patience is exhausted by a long protracted, though less painful illness, may be fretful and peevish, may be insensible to the kindness of his most zealous friends, and may receive their attention without the smallest acknowledgment of gratitude, or may even repay it with rudeness. But let not us be peevish and angry in return; let us consider what I have just mentioned as symptoms of corporeal disease, which should excite in us no other sentiment than that of commiseration. We owe this to the sufferings of human nature; we owe it also to ourselves; for if we were to look upon the case in any other point of view, our feelings would be continually outraged. A similar allowance is to be made for those whose anxiety for themselves, or for their friends, leads them to perplex us on less important occasions with a number of trifling, and perhaps unanswerable questions. Be, if you please, brief in your communications, but bear in

mind, that whenever you lose your temper, you lose also your influence over your patient, and expose yourselves to the attacks of calumny and ill-nature. Connected, as we are, with the whole of society, and society being composed of individuals having such diversity of characters, you will not be surprised that you should find some who will repay you for your professional attentions with gratitude beyond that which you have a right to claim. You will also not be surprised if you find some persons who, from their own mistake, from the misrepresentations of others, or even from the natural bad dispositions of their own minds, will be led to conduct themselves differently towards you; will blame you where you deserve credit; will lay to your charge the evils which the natural and unalterable course of events, or their own irregularity and folly, has brought upon them; or will attribute to you some gross error or negligence, where no error has ever been committed; where you have actually been devoted to their cause, and have rendered them the most essential service. This, however, is not our peculiar lot; it is the lot of all those whose profession connects them with the world at large;—the minister of state, the leader of armies, the judge, the barrister. Far be it from me to advise you to compromise the dignity of your professional character by quietly submitting to injurious treatment; but, nevertheless, I must caution you, that you do not, by any act of hasty resentment, give an advantage to those who are ill-disposed towards you. Be prepared, in the outset of your practice, for these things, not indeed as a frequent, I may say as a rare occurrence; and as far as in you lies, on such occasions, let a feeling of contempt and indifference supersede that of anger and mortification.

We have all heard a great deal said respecting the manners of medical men. It appears to me, indeed, that many attach more importance to this subject than really belongs to it. It is true that it is desirable that the external behaviour of a physician or surgeon should to a certain degree correspond with that of the particular class or classes of society among whom he may be professionally employed. It is true that it is of consequence to the comfort and satisfaction, both of the patient and himself, that he should impress the former with sufficient confidence as to his skill and knowledge. It is true, also, that brutal and unfeeling manners, offensive as they are in all persons, must be especially so in one of us; and that no individual can be satisfied with the attendance of a medical practitioner who seems to be indifferent and careless as to the favorable or unfavorable result of his case. But all this brings us back to some very simple rules of conduct. Lose no opportunity of acquiring knowledge, for know-

ledge will give you confidence in yourselves; and that will enable you to inspire others with it also; at least you can depend on no other means employed for that purpose. An ignorant person may indeed, by silence and solemn looks, occasionally obtain the credit of knowing that with which he is actually unacquainted. But the deception is not permanent; the mask will sooner or later drop off; and explanations and subterfuges will only serve to render his ignorance more manifest. Again, it is necessary that you should have the earnest wish to contribute all that is in your power towards your patient's welfare, and leave no method unemployed which is likely to be of service to him. Mere professions of interest are of little value; they are too flimsy not to be easily seen through, if unaccompanied by active exertions; and if such exertions be not wanting, professions are unnecessary. I repeat that, if you have a competent share of knowledge and skill; if you possess a feeling of kindness towards your patient, and an earnest desire to do the best which can be done for the relief of his sufferings, your manners will form themselves, and you need have no further anxiety respecting them. To adopt any less honourable artifice, is beneath the dignity of our profession. Be it observed, moreover, that natural manners are rarely otherwise than agreeable; while artificial, and affected manners, are almost invariably the reverse. There can be no greater mistake in conduct, not only on this, but on all other occasions, than to imitate the manners of another person. A tall man, who puts on the coat of a short one, is less ridiculous than a person who assumes the manners belonging to a character that is different from his own.

I may here, without impropriety, advert to another subject, to which the consideration of that of which I have just spoken in some measure leads us. We are called upon, in the majority of instances, to give an opinion to the patient and his friends as to the nature of the disease under which he labours, and its probable termination. This part of our professional duties requires much judgment and consideration. It is evident that a complicated case will require a careful investigation; during which, one circumstance may, in the first instance, incline you to one opinion, and another circumstance may afterwards incline you to another opinion, and you may not be able to satisfy yourself that you have arrived at a correct diagnosis until after much hesitation and doubt. But these difficulties are not to be communicated to the patient. He can have no interest in any thing but obtaining the ultimate result of your inquiries. Thinking aloud on this, as on all other occasions, is most injudicious, leading to perplexity and confusion, always lessening, and not unfre-

quently destroying, the confidence which you would wish to have reposed in what you say. You are not called upon to inform others of what passes in your own mind until your investigation is completed; then deliver your opinion simply, and as free as possible from technical expressions, so that it may be easily comprehended; and you will use your own discretion in each particular instance, as to whether you should or should not explain the grounds on which that opinion rests. It appears to me that you are called upon, as a matter of propriety, and even of good policy, to communicate to your patient the actual state of your own knowledge of his case; to place before him, as nearly as possible, the view which you have been led to take of his present condition and future prospects. The circumstances are very rare, indeed, which authorize you to deviate from the rule of telling truth. It is of the utmost importance both to your patient and yourself that he should believe what you tell him: and how can you expect him to possess faith in what you say, if his experience convinces him that you have in any way deceived him? Moreover, if you endeavour to represent things as different from what they really are, it will be impossible for you, in the course of a long attendance, to avoid being involved in numberless contradictions. I will grant, however, that circumstances may occur which will make it unadvisable, and even improper, that you should disclose at once to your patient the whole of what you know. For example: if a person labouring under a severe and acute disease be informed of the full extent of his danger, the influence of this upon his mind may very materially diminish his chance of recovery. If you are consulted by a patient who labours under some chronic affection, of which you know that it is absolutely incurable, and that it must, in spite of all the exertions of your art, go on inevitably, though perhaps slowly, to his destruction, it is rarely (I may say it is never) justifiable for you, in the first instance, to make him aware of the whole extent of his calamity. The shock may be more severe to some than it is to others; and, for the most part, it will be greater to those who have enjoyed uniform good health and an uninterrupted flow of spirits, than to those who have been in some measure prepared by occasional attacks of acute disease, or constant, though slighter, ailments; but, though in different degrees, still it will be a shock to every individual of the human race, to have the intelligence of his labouring under a mortal and hopeless disease communicated abruptly to him. Be not deceived on these occasions by the representations of the patient. Those who say to you, "I wish to know exactly my own situation; if you tell me that I am to die to-morrow, I am per-

fectly prepared for the event," are often the persons who are, in reality, the least fitted to receive such a communication. Observe that I am now speaking of your conduct in the first instance, when you are first consulted, or at least when you have first ascertained, beyond a doubt, the desperate nature of the case. Afterwards, your conduct must depend on the peculiar circumstances in which the individual is placed, or on his peculiar turn of mind. It may be of the greatest importance to his family that he should be apprised of his approaching dissolution, that he may have the opportunity of arranging his worldly concerns, for their future benefit; or, in the progress of his disease, his mind may have become gradually so habituated to the contemplation of what may possibly occur, that he may look forward to death, as the end of his sufferings, with satisfaction, instead of dismay; and surely it will then be right not to withhold from him that information which will be useful in the one instance and consoling in the other. Again, there are persons who cling to the hope of some favourable change to the very last; who, even when they cannot but, on reflection, be convinced that all reasonable expectations of recovery are vanished, will still receive with gratitude a look or a word which signifies to them that the smallest amendment has taken place. Here you will study your patient's natural disposition, not forgetting that, where you cannot heal the body, you may still be of some service by affording consolation to the mind: and this may be accomplished, in general, without any actual departure from the truth, by avoiding to notice those things which indicate an alteration for the worse, dwelling on trifling alterations for the better; and dexterously managing your conversation, so as to avoid giving direct answers to such questions as, if answered, must lead the patient to a too intimate acquaintance with his real condition. The management of incurable and hopeless chronic cases is one of our most painful, but it is at the same time one of our most important, duties. In the outset of my professional career, I was accustomed to feel as if it were scarcely just and conscientious to continue my attendance on a patient under the circumstances which I have described, whose disease was entirely beyond the reach of art. I feel differently at present. You may generally lessen actual suffering, even where you can render no more essential service. You may soothe and tranquillize, and even cheer the sinking heart. Moreover, human nature is so constituted, that either the patient or his friends will look for assistance to the very last. If you withdraw your attendance because you can do no positive good, another person may intrude himself with vain promises, who will do positive evil; and thus an honourable

and well-intentioned practitioner may save a suffering fellow-creature from becoming the victim of impostors and quacks.

I trust that you will find hereafter that I have not occupied your time altogether unprofitably, in drawing your attention to some of the more essential circumstances connected with professional conduct. Be assured that, in so doing, I have endeavoured to avoid being influenced by theoretical views. The remarks which I have made, such as they are, have been suggested by the serious consideration of what has occurred under my own observation, and in the course of my own experience. Giving, however, to these inquiries all the importance which they deserve, it must be allowed that the investigation of the history, the symptoms, and the treatment of disease, is more important still; and this leads us to another subject: what are the qualities and habits of mind which are the most useful in these latter studies; by means of which you may be the best fitted for the acquirement of surgical knowledge and the application of it to practice?

You will soon discover that persons whose minds are very differently constructed, may, nevertheless, attain the same degree of professional reputation and character; and no individual is to be disheartened, or dismayed, because he finds that he is deficient in some one quality through which another has been enabled to excel. In the profession of the law, we have seen the strong intellect of Thurlow, and the genius and imagination of Erskine, afford to each of them the means of becoming elevated to the same high station; and in ours, that which one individual accomplishes by superior sagacity, another may accomplish by greater diligence and application, or by a more perfect development of the faculties of thought and reflection. Nevertheless, if, with poetic license, we were to pourtray an ideal character of an individual more eminently qualified than any one whom nature has created for the comprehension of our sciences and the practice of our art, we should undoubtedly represent him as possessed of various intellectual endowments: and although we may thus be led to form a conception of that which the efforts of man will never realize, yet it cannot fail to be of advantage to us that we should, while engaged in our professional pursuits, be in the habit of measuring ourselves, not so much by that we see in real life, as by this imaginary standard. This will not only prove the best antidote to the follies of conceit and vanity, but it will afford us a better opportunity than we should have otherwise of discovering in what respects we are deficient, and what are the particular faculties and powers of mind which require in each of us to be exercised and strengthened.

One thing, then, which is very necessary to us is, that we should be habitually accurate and minute observers of individual facts. We should watch the smallest changes which occur in the progress of a disease; we should extend the same careful observation to the appearances which are disclosed by the inspection of the dead body, and the operation of remedies. Some persons may naturally be gifted with the faculty of minute observation in a greater degree than others; but in the former it may be impaired by neglect, and in the latter it may be improved by cultivation. There are some cases of disease in which little else than what I have just mentioned is necessary for them to be understood; in which this is almost alone sufficient in their right diagnosis and treatment; for example, fractures, dislocations, wounds of muscles and tendons, exostoses, and various other diseases, which are situated externally, and are not connected with derangement of the general system. It is equally necessary in cases of greater difficulty, where the disease being situated internally, is not at once cognizable by our senses; or where it proves a part of some constitutional affection. But here other and higher faculties are necessary also. We must trace the resemblance which exists between different diseases, and we must at the same time note the points in which they differ from each other; we must compare the present symptoms with the past history; we must reflect and reason, and weigh probabilities. It is the power of rightly and readily calculating probabilities, which, in our profession, as in the common affairs of life, constitutes the man of judgment, and I need scarcely say in what a multitude of instances, where positive and demonstrative evidence is wanting, this power requires to be exercised.

That inventive faculty, which combines, and abstracts, and perceives, remote relations and analogies, which we denominate genius, may not be necessary to the obtaining an accurate knowledge of what is already known, nor to the judicious exercise of the established rules of surgery. But let it not, therefore, be rejected as a thing that is useless and unprofitable in our pursuits. It is far otherwise. It may afford the means of throwing some new light, not only on the rare and dangerous, but even on the most common and trifling cases: and let me ask if it was not the genius of the Hunters which first discarded the clumsy mechanical and chemical doctrines, which formerly prevailed in the medical schools, and led to the establishment of that new philosophy, in which all modern improvements and discoveries, connected with medicine and surgery, may be said to have had their origin.

Diligence, perseverance, application,—let not these be regarded as inferior and subordinate qualifications. They are quite

compatible with the brightest genius ; and, in fact, genius can accomplish nothing that is truly great without them. Unless you have the power of keeping your attention fixed for a length of time on one object, you will not be able properly to investigate any case of complicated disease. Beware how you habituate your minds to be constantly wandering from one subject to another. It is a good rule to be observed on all occasions, that your attention should be devoted to the subject before you, and not directed to any thing else, until you have examined it on every side, so as perfectly to comprehend it.

Need I tell you, that presence of mind and self-possession, important as they may be under all circumstances, are especially so in operative surgery. Much here, undoubtedly, depends on physical constitution ; and what is easy to one person may be, comparatively, difficult to another. Nevertheless, the best foundation of these qualities is the confidence which is the result of knowledge ; while that confidence which arises from insensibility and ignorance is worse than timidity.

It appears to me not improbable that at the conclusion of the present lecture some of those whom I now address may feel disheartened at the prospect which lies before them, when they consider how extensive are the acquirements which are necessary to the medical practitioner. To understand the natural structure of the human body, and its healthy functions ; to understand also the numerous varieties of disease, and the operation of remedies ; to learn the control of our own feelings and conduct, and to study and know the hearts of others ; all this, they may say, is too much for an individual to undertake. Wherefore should we not turn aside to some other profession which is less difficult and arduous ? Gentlemen ! there is none among the more liberal and enlightened professions, concerning which, if its various duties be considered in the detail, a person, who has just entered on his studies, may not be inclined to make a similar observation. But, bear in mind, that no one is expected to embark in the practice of a profession perfect in knowledge and in conduct. This is the work, and ought to be the great object, of a man's life ; and that which it would be impossible for us to effect in the brief space of a few months, we may accomplish by means of constant attention, and of efforts continued for many successive years.

If time permitted, I might say much to you in favour of that profession which you have chosen for your own. Is there any science more curious, more interesting, more comprehensive, more sublime, than that which relates to the phenomena of life ? and is not this science the basis of medical and surgical knowledge ? Our profession,

above all others, admits of a manly independence of character in those who pursue it properly. The public, or that portion of the public to which you belong, will be your patrons : perform your duty towards them ; lose no opportunity of improving yourselves in knowledge ; practise your art honourably, and you will never find occasion to cringe or stoop, in order that you may procure the favour of any individual. You will make your own place in society ; and certainly need not feel yourselves inferior to those, who, reposing on the advantages of artificial rank, or of hereditary wealth, pass their days in trifling occupations, and seem to think that, born for themselves alone, they are not called upon to contribute *their* exertions towards ameliorating the condition of the human race.

I shall trouble you with only one observation more. It may be said of our profession, that, unlike most others, it has for its constant and sole object to confer benefit on others. The advocate, at one time, pleads for the guilty ; and at another endeavours to convict the innocent. The soldier engages to go wherever he is sent, that he may destroy the lives of those from whom he never received an injury : but the physician and surgeon are engaged only in lessening the afflictions, and prolonging the existence, of their fellow-creatures.

OBSERVATIONS

ON

STRICTURES OF THE RECTUM.

BY HENRY EARLE, F.R.S.

To the Editor of the Medical Gazette.

SIR,

HAVING had occasion lately to examine the body of a child, aged 15 months, who died of hydrocephalus acutus, I was struck on opening the abdomen with a very remarkable deviation from the usual course and length of the large intestine. The descending colon, on gaining the brim of the pelvis, instead of proceeding downwards to form the sigmoid flexure, suddenly took an upward direction under the arch of the stomach, crossed obliquely to the right iliac region, and then descended to form the rectum. The portion of intestine above described was more than 12 inches in length, and was free in the cavity of the abdomen, being quite enveloped in peritoneum, like a small intestine, and having a reduplication of peritoneum similar to the mesentery, of three inches in length. It was not sacculated like the rest of the colon, having no visible longitudinal bands, and in every re-

spect, except its volume, it bore a close resemblance to a portion of small intestine. It was so loosely connected, and so pendulous, that it might very easily have been included in a hernial sac on the *right* side. I have considered this fact deserving of being recorded in your valuable journal, not only from its being peculiar, but from the important practical inferences which may be drawn from it. I have many times met with similar deviations to a less extent, more especially in female subjects, where the colon will often be found to cross over to the right side before descending to form the rectum. I had occasion to mention this circumstance last spring, in some clinical observations on a case of diseased rectum; and in the course of the same week two instances occurred in examinations which were made in the dead-house, illustrating the truth of the position. I mention this to prove that it is by no means a rare occurrence, though in no work on anatomy, which I have perused, is any mention made of such a deviation.

The importance of every surgeon being aware of the possibility of such an occurrence, will at once strike your readers, when it is considered what serious and even fatal injury might ensue from a surgeon attempting to pass a rectum bougie according to the prescribed rules, in such a case. He would infallibly meet with resistance, which he would probably mistake for stricture, and if he employed any degree of force, he would lacerate the bowel, and destroy his patient; for, be it remembered, that this accident is far more likely to occur when the coats of the intestine are healthy than when they are thickened by disease. This was the case in an instance which lately formed the subject of a judicial inquiry; the intestine was quite free from the semblance of stricture or disease, and consequently was more easily lacerated by the degree of force employed to overcome the imaginary stricture; and here, sir, I will take the liberty of offering my testimony on the subject of strictures of the rectum—a testimony founded on upwards of twenty-four years' practice in the largest hospital in London, and on examination of most of the collections of morbid preparations.

It is my firm conviction that strictures at the sigmoid flexure, or higher up, are very rare occurrences in-

deed. The most common seat of disease of the rectum is from two to five inches up; a part which can always be satisfactorily examined with the finger of the practitioner, or with the assistance of a speculum ani.—When stricture is said to occur beyond this, I should always be inclined to be sceptical, as many circumstances render it very difficult, if not impossible, to ascertain the fact during life. In some instances I have no doubt the gut takes the direction which it was the object of this paper to explain; in others, the promontory of the sacrum projects so as to mislead the practitioner; in others, again, there may be enlargement of the ovary, or other tumors in the pelvis, which may afford an obstacle to the introduction of instruments. These circumstances may, and I have no doubt have often, misled surgeons. But I fear this excuse cannot be offered for those who would represent stricture of the sigmoid flexure of the rectum as one of the most frequent maladies which flesh is heir to. Such men, I fear, are more inclined to deceive others than to be the dupes of their own imperfect knowledge. If this were not the case, why should they be so over anxious to keep their patients in ignorance of the real state of their bowels, by the daily exhibition of purgatives, when the appearance of one natural evacuation would undeceive them and their patients, and would afford more satisfactory evidence of the actual state of things, than all the bougies that were ever invented? I trust that I shall not be considered improperly severe in thus exposing a growing evil, and warning the rising generation from listening to the plausible assertions of men who betray the sacred trust conferred upon them, and who prefer the acquisition of lucre to the honourable discharge of the duties of their profession.

To return from this digression: there is yet another circumstance which induces me to attach importance to the fact which called forth these observations, namely, the light which it tends to throw on an affection of the rectum which occasionally occurs, and which is productive of much distress and inconvenience to the patient. The affection to which I allude has been described by the late Mr. Chevalier, under the title of "*Relaxed Rectum*," in a paper published in the *Medico-Chirurgical*

Transactions, vol. x. Mr. Chevalier considers the affection as "a semipro-lapsus of the upper part of the rectum into the lower, in consequence of great dilatation of the gut from accumulation of fæces." I shall proceed to describe the affection, as I have met with it in many instances in the living subject, and as it appeared on investigation after death, in one case which I had an opportunity of examining.

In examining a patient suffering under this affection, it is indispensably necessary to make such examination with the finger, as no bougie, however skillfully employed, will convey any just impression of the nature of the malady. On passing in the finger it is not uncommon to find some spasmodic contraction at the anus, the circumference of which is generally more or less surrounded with hæmorrhoidal excrescences. Immediately on passing the sphincter ani, the finger enters into a large cavity very much exceeding the natural dimensions of the gut; and here I would observe that before making any such examination the bowel should be well cleared with enemata. If the finger be passed on and carried round this large cavity, numerous loose pendulous folds of relaxed mucous membrane will be felt readily yielding to the pressure of the finger. In some cases the finger will detect, in the midst of these loose folds, a portion harder and more resisting than the rest, and of a circular form. On carefully tracing the outline of this circular opening, which has much the feel of a slightly dilated os tinæ, the outer margin will be found to gradually terminate in a *cul de sac*, of greater or less depth, according to the extent of the introsuscepted portion of gut. This state of the bowel can be felt only in those cases where the introsuscepted portion has descended near the anus. When it occurs higher up in the rectum, beyond the reach of the finger, all that can be detected is the large cavity surrounded with loose folds of thickened mucous membrane, and the muscular coat of the gut appears to have lost its contractile power. In making this examination in a female, the uterus will be found unusually low, and drawn backwards into the concavity of the sacrum. Not unfrequently, the uterus is enlarged, and the bowel is much thickened at the surface corresponding

to that organ. In such cases, if the fore-finger of the other hand be introduced per vaginam, at the same time that examination is conducted per anum, the uterus will be felt partially retroverted, and, on attempting to raise it, the corresponding portion of rectum will be found to move with it: preternatural adhesion will, in fact, be found to exist between the peritoneal surfaces of the rectum and uterus. When this introsusception exists in the lower part of the rectum, it may be confined to the mucous coat of the intestine, as Mr. Chevalier supposes; but when higher up, the whole thickness of the bowel descends; and if the affection be not soon relieved, more or less adhesion will take place between the surfaces, and the prolapsed portion will become thickened and contracted, forming a permanent stricture of the most obstinate kind. Such was the impression of the nature of this affection, conveyed by an examination of many cases in the living subject; only one opportunity has hitherto occurred of investigating the subject further, and ascertaining the actual state of parts by anatomical investigation. The instance in which this occurred was an exceedingly aggravated case, where other morbid changes had taken place, and the mucous membrane of the intestine was in a state of ulceration. Extensive firm adhesions were formed between the peritoneal surfaces of the rectum and uterus. The latter organ was enlarged and displaced, forming almost a valvular obstruction to the passage of the fæces. About an inch and a half of the whole circumference of the rectum was introsuscepted, forming a remarkably firm indurated stricture, commencing a little below the promontory of the sacrum. Below this portion the rectum was enormously distended, the mucous membrane thickened and discoloured with numerous tortuous veins, rendered varicose by the pressure of the firm condensed mass above. In patches, ulceration of the membrane had taken place at and above the stricture. On tracing the bowel upwards, I found that it took a direction to the right iliac symphysis, then crossed over from the right to the left side, and terminated in the descending colon.

On considering this subject maturely, it appeared not improbable that a predisposition to this form of introsus-

ception might be traced to this natural deviation from the usual course of the intestine, and its being loose and pendulous immediately above that portion which is firmly bound down in its situation by the fold of peritoneum known by the name of mesorectum. The not unfrequent occurrence of this deviation, more especially in females, who are most disposed to this affection, induces me to offer this explanation to my professional brethren, to be confirmed or confuted by subsequent investigations. Mr. Chevalier, in the valuable paper above alluded to, refers this state of semiprolapsus to habitual costiveness, and inattention to the due performance of the natural functions. By thus allowing large quantities of faecal matter to collect in the rectum, its cavity becomes preternaturally enlarged, and its muscular parietes lose their contractile power. To expel the contents of the rectum, a greater exertion of the abdominal muscles is rendered necessary, by which Mr. C. conceives the upper undilated portion of the rectum is forced downwards into the lower dilated portion. This solution of the immediate cause of this affection is ingenious, and may, in many cases, be correct; but I have met with others, and have one at the present moment under my care, in which this state of gut exists in a very aggravated degree, of which the previous history will by no means admit of such an explanation, as the patient was never subject to constipation until very lately, until, indeed, those alterations which have been described had actually taken place, which so interfere with the mechanism of the parts (if I may use the expression) as materially to interrupt the due performance of their natural operations. In such cases, I conceive Mr. Chevalier may have confounded cause with effect, and have referred to the relaxed state of the lower portion of gut as the cause of the prolapsus, when, in point of fact, it may have followed as a natural consequence of such prolapse, the effect of which would be mechanically to interfere with the due muscular contraction of the lower portion of gut upon its contents. In such cases, I conceive it not improbable that there may have been a predisposing cause referable to the loose and pendulous state of gut which I have already endeavoured to explain.

It remains for me to give some account of the symptoms which characterize this affection, and the means best adapted for their relief. Patients suffering under this complaint, are sometimes liable to the symptoms common to all permanent obstructions of the rectum—namely, a frequent desire to evacuate the contents of the bowel, great difficulty in effecting this, and an unsatisfactory feel of not having effected the object immediately after an alvine evacuation. This induces them to strain and exert the abdominal muscles, which tends much to aggravate the mischief, which thus may be said to ingender the seeds of its own increase. They are liable to great distention of the colon, with wind and scibalous portions of faeces, causing severe abdominal pains, and a sense of weight and uneasiness on the left iliac region. The greatest difficulty is experienced in voiding the accumulated flatus, which rarely passes without a discharge of faeces. A sense of weight is felt in the pelvis, and the lower extremities have a peculiar feeling of cold and numbness, sometimes amounting to partial paralysis. At other times, patients suffer from spasmodic pains and cramps in the muscles of the legs. The uterus in the female, and the prostate gland and bladder in the male, participate much in this affection. There is a constant sense of bearing down and profuse leucorrhœa, with frequent micturition, which occasionally lead to the supposition of the uterus or bladder being the actual seat of disease. A lady, whose case I have already alluded to, was for several years treated, by the late Mr. Pearson, for a supposed incipient cancer of the womb. In another instance, a patient had been ordered, by a very eminent surgeon, to have issues made in the loins, under a supposition of the existence of disease in the spine, in consequence of the numbness in the lower extremities. In addition to these symptoms, which are more or less common in other cases of diseased rectum, there are some which are peculiar to this affection. From the large cavity which exists below the strictured or prolapsed portion, very large accumulations of faeces occasionally take place. Patients, under these circumstances, have frequent calls, which they obey; and as they void something, however small, it tends to mislead them, and to induce

them to give a very erroneous account of themselves. Thus, when the state of the bowels is inquired into, the ordinary reply is, that they are quite open—indeed, that they have very frequent evacuations. This may occur, and yet an enormous quantity of hardened feces may be still retained in the dilated and nearly palsied gut, which will often require mechanical aid, in addition to the employment of soft soap and other enemata. At other times patients are incapable of retaining the feces, if at all liquid, as soon as they descend through the prolapsed portion into the lower cavity. In such cases the power of the sphincter ani is much reduced. Patients have sometimes distinctly described the difficulty experienced in passing the contents of the colon through the stricture, and their want of command either to expel or retain the feces when they had so descended into this cavity. Much inconvenience is experienced in consequence of this when active purgatives are administered.

Another marked symptom which occurs in this case is the frequent and, at times, copious involuntary discharge of mucus from the irritated mucous membrane lining the pouch or cavity. This being generally discoloured, leads to the supposition of some internal abscess having broken.

In the treatment of these cases the great object to be attained is to restore the prolapsed portion of bowel, or relaxed mucous membrane, to its proper relative situation; and this is to be attempted by the use of soft wax bougies, of from six to eight inches in length, and the habitual employment of injections. When a bougie can be successfully passed into the aperture of the gut, and the prolapsed portion gently carried upwards, patients experience great and well-marked relief. The bougie not only supports the bowel in its situation, but in the female it acts as a pessary, and by supporting the uterus, relieves all the distressing symptoms depending on the retroverted state of that organ.

This plan of treatment, combined with injection and the mildest purgatives, will in some rare cases, fortunately taken at an early period, effect permanent relief; generally speaking, however, it is only in our power to palliate the symptoms, and afford tem-

porary alleviation by the judicious employment of the same means.

In making use of the bougie in these cases, the surgeon is particularly liable to be misled, and to fancy that he has succeeded in passing the instrument through the stricture, when, in fact, it has never entered it. This deception can only be detected by following the bougie, after its introduction, with the finger, when, in very many cases, it will be found coiled round in the large loose cavity so often alluded to; and it sometimes happens that in making this examination, the actual opening or continuity of the bowel is first detected, from the folds of relaxed mucous membrane being expanded by the coils of the bougie. The common source of failure in introducing the bougie arises from the extremity of it passing into the *cul de sac*, which surrounds the rim of the prolapsed portion of bowel: a degree of resistance is at first felt, which after a time yields as the bougie becomes softer, and it will now pass on with comparative ease, in consequence of the point having turned downwards, and the bougie coiling round in the concavity of the sacrum. This error may sometimes be detected at the time when it is committed—namely, at the moment when the obstruction is apparently giving way: if the surgeon quits his hold of the bougie at this moment, it will recoil upon him in the same manner as when a wax bougie becomes twisted in the urethra: on the contrary, when it enters the stricture, it will be steadily retained there, and will even afford some resistance to its being withdrawn. It might at first be supposed that such an error as I have described could be detected on the removal of the instrument; and so it may be, by an experienced eye, well acquainted with the appearances produced by real stricture of the gut, and these fallacious indentations and impressions caused by the sudden twisting of the softened bougie within the cavity of the rectum; but to the uninitiated, these marks will be considered as proofs of the existence of stricture, which they imagine they have passed. I may appear tedious in dwelling thus on this subject; but so much depends upon the proper application of the bougie, and from long experience I well know the great difficulty in some cases attending this apparently simple opera-

tion, that I have endeavoured to convey to others all the information in my power.

In some cases I have found it necessary to employ a well-polished metallic tube, like the French *speculum vaginae*, which I have passed into the lower cavity, and having, with the assistance of a lighted taper, observed the opening of the bowel, have passed the wax bougie through the metallic tube, and having entered the stricture, I have then withdrawn the metallic tube, and carried forward the bougie. In other instances I have employed the fore-finger of one hand in the vagina to direct and steady the application of the bougie with the other, and to ascertain whether it had turned or not. With all these precautions, and this knowledge of the nature of the difficulties to be overcome, I am willing to acknowledge that I have been often foiled; and I feel quite confident in making this assertion, that many who fancy that they have succeeded, would have been undeceived if they had taken the trouble to introduce the finger either per vaginam or per anum, after the bougie had been passed into the cavity of the gut. When the bougie has been passed quite through the contracted or prolapsed portion, it should be gently urged on, until the whole instrument is passed beyond the sphincter ani, leaving only a fine soft piece of narrow ribbon protruding at the anus. The bougie so introduced, if it produces no irritation, may be left during the whole night and part of the day, until the patient requires to empty the bowels. On removing it, a natural and better formed evacuation will often follow. When patients are well informed and handy in the use of instruments, I always endeavour to teach them to introduce the bougie for themselves, which they will sometimes effect much more readily than any surgeon, from their own feelings guiding them in its proper direction.

By persevering in the use of this for some time, patients become very adroit, and experience much comfort and relief. In addition to this, it is necessary to empty the bowels with enemata, conveyed through an elastic gum tube of some inches long, which should be introduced into the prolapsed portion of the gut. The common short ivory pipe often fails to convey the injected fluid beyond the lower cavity, and hard fœculent matter

may be detained above the contracted part, which the injection never reaches. When there is much mucous discharge from the lower cavity, the injection of a solution of alum, or the chloride of soda, will be found very beneficial in arresting this discharge, and corrugating and restoring tone to the dilated bowel: opiates and other palliatives may be occasionally resorted to.

But it is time that I should now conclude this communication, which has already much exceeded the limits I proposed. I trust that sufficient has been said to induce others to make observations respecting this unusual course of the large intestine, and the probable diseases to which it may give rise; and I hope, by calling the attention of medical men to an affection of the gut but little understood, that the sufferings of many may be alleviated, if not permanently cured.

I am, Sir,
Your most obedient servant,
HENRY EARLE.

28, George-Street, Sept. 27. 1829.

ACCOUNT
OF A
LIVING DUPLEX CHILD.

Communicated by CHARLES BELL, F.R.S. to whom the letter is addressed.

Teddington, 17th Sept. 1829.

MY DEAR SIR,
A RECENT excursion to Switzerland gave me occasion to see, on the 1st of August last, at Geneva, a remarkable example of a living *lusus naturæ*, or monstrosity in the human frame; namely, twin infants furnished with two heads, two necks, and four arms, but grafted or united side to side, so as to form only one female body, terminating in two legs, or inferior extremities of usual shape. This phenomenon presents nothing disgusting to the beholder; on the contrary, the intelligence which already begins to develop itself in the heads, makes it an object of great interest. I had not the opportunity of a very minute personal examination, in consequence of only seeing it at the hour of its daily exhibition to the public; but my observation verified the accuracy of the subjoined description,

by Mons. F. Mayor, which was published in the *Journal de Genève* of the 30th of July:—

Marie-Terèse Parodi, 32 years of age, the mother of several perfect children, gave birth on the 12th of March of the present year to a double child, now 140 days old. The one to the left was baptized by the name of Christina, the other by that of Harriet.

At the first glance it is perceived that twin infants have become grafted together: however, when they are regarded from before, the lower parts of the body appear simple from the stomach downwards, while the chest is divided at its upper part, at least on one side of the trunk. A more attentive examination speedily enables us to recognise the following peculiarities:—

~~Anteriorly, the chest only appears to form one thorax:~~ the sternum forms a kind of gutter at its inferior part, while above it widens and enlarges very much, in order to give attachment to four well formed clavicles, two of which are fixed at the external angles of that bone, and the other two at the middle of its superior border. Each of these four clavicles is directed towards one of the shoulders, and gives all the support necessary for the movements of the arms, of which two are placed between the heads. The right edge of the sternum appears to give attachment to the right ribs of Harriet, and the left to the corresponding ribs of Christina. There are ~~four~~ ^{two} mammae, the two in the middle being smaller than those which are external to them, and are encroached upon by the arm-pits of the middle set of upper extremities. There is but one umbilicus. When the examination is made from behind, two spinal columns are distinctly seen, sufficiently separated from each other at the upper part of the body; but they approximate towards the sacrum, of which there are two, united by the left edge of the one and right of the other, in such manner, however, that the ossa coccygis are quite distinct. From each vertebral column there arise ribs, which are directed towards each other: the four or five first run to the anterior sternum; but the rest are united to those of the neighbouring body, at least by their external surface, and appear only to form one circle with those of the anterior part of the trunk. Thus,

then, the thoraces are really separated externally throughout their upper third, and probably entirely so within: the posterior ribs of this double trunk participate in the movements of respiration in the same way as those of the anterior part. The beating of the heart in Christina is perceived at the anterior and left surface of the trunk; the beating of the heart in Harriet is seen at the middle part of the posterior surface. Beneath the ribs of this same side there is, between the two spinal columns, an abdomen twice as small as that on the anterior surface of the trunk. Harriet has had from her birth some malformation of the breast, for it is not long since the blueness with which she was affected began to disappear. For some days she has had a catarrhal affection, and her pulse was at 168 in a minute, while her sister enjoyed perfect health, the pulse not exceeding 144 in the minute. Their breathing is not always synchronous; however, there is reason to believe that a communication exists between the lobes of the lungs of the two children. The one sometimes sleeps while the other is awake—sometimes sucks while the other plays, or wishes also to get the breast; but never has one an evacuation without the other making the same efforts, which even wake her, if asleep. As they grow older, other and yet more interesting phenomena will doubtless be observed.

Examples of this kind of union are happily but little common, and it is but rarely that they survive their birth. A good many cases, indeed, are mentioned by authors, but most of them are apocryphal; some, however, are well authenticated; such, for example, as the two Hungarian girls, spoken of by Buffon, who were united by the loins, and who lived 21 years. Another case of a similar kind occurred at Verdun, in 1709: here also two females were united, and in the same manner: they were then seven years of age, and could walk; and their intelligence was so great that they had acquired several languages. There is also an instance in which two little girls were united from the lower part of the sternum to the umbilicus. The accoucheur divided the parts, and thus separated by an operation, the children lived.

In 1495, there were born near Worms, twins united by the forehead: they lived for ten years, when one died,

and the other was separated by an operation; but it proved unavailing. In 1525 a native of Savoy, 30 years of age, and of the ordinary stature, exhibited himself. He had hanging from the sternum a body about a foot in length, having feet and arms, but without motion, while the head appeared as it were planted in the body of the man. In 1533 there was in Bavaria a female mendicant with two heads, who was driven from the country lest the pregnant women should give birth to similar monsters—a fear as imaginary as the result of it was cruel and uncharitable. Buchanan, in his History of Scotland, mentions the case of a monster with two heads, which lived 28 years. The two heads having different volitions, often quarrelled. They both felt wounds of the lower part of the body, but those of the upper part were only perceptible to the corresponding head. In 1552 a French woman at Geneva, was brought to bed of a monster, the heads of which were united by the posterior part, and the union extended to the lower part of the back. Gaspard Materier took a portrait of it. The monster lived some hours, and is compared to Janus by a writer (Lycosthene) who describes it.

Before we conclude we may allude to the opinion which has been frequently started and recently renewed, that such monsters ought to be destroyed immediately after their birth. *No one can have a right to do so*; for since God ordains that such beings should come into the world, the laws owe them protection. Besides, it would be very difficult to determine the degree of imperfection at which an infant would cease to have a right to live; for these phenomena are met with from a simple supernumerary tip of the ear, up to the example above mentioned, of two girls who were successfully separated by an operation.

The catarrhal affection, with febrile excitement, under which the twin named Harriet laboured on Thursday the 28th July, noted by M. Mayor, had subsided on the 1st August, and she then had an appearance as healthy and lively as Christina. Both infants seemed to exercise some control over the motion of the lower limbs; but should they live until their mental faculties and animal powers are further developed, it will become a matter of curious inquiry to ascertain in what manner nervous in-

fluence, springing from two distinct organs of sensation and volition, shall be directed towards the lower extremities, so as to effect locomotion in accordance with the will of each sensorium; or whether there shall be occasional contentions between the *heads* for a dominating power over the *legs*.

Although the precise peculiarities of structure in the abdominal viscera, and the question as to whether the internal organs of generation correspond in unity and simplicity with the external, are points which cannot be fully determined till after death, yet, from the circumstance of each infant taking food with avidity, at different times, it may be inferred that each has its proper stomach, and that the union of the alimentary canal takes place below that organ.

Many facts desirable to be ascertained hereafter, during the growth of this extraordinary animal phenomenon, must arise, referring especially to anatomy and physiology; and as you have been long an eminent professor of these branches of medical science, I am induced to address to you this letter, in the belief that it may invite you to gratify your own zeal, and to indulge that of the profession, by instituting farther inquiries, from time to time, regarding the interesting subject of it.

I remain, my dear Sir,

Very faithfully yours,

J. BORLAND.

NEW OPERATING TABLE.

To the Editor of the London Medical Gazette.

Cheltenham, Sept. 2, 1829.

SIR,

By the recommendation of Sir Astley Cooper, and the known popularity of your work, I am induced to forward you the enclosed, and shall feel obliged if you will give the description and the drawing an early place in your valuable pages.

I am, Sir,

Very truly, yours,

CHARLES AVERILL.

Description of a New Operating Table, in use at the Cheltenham Casualty Hospital, by CHARLES AVERILL, Surgeon to the Institution.

Whoever has witnessed the frequent

performance of surgical operations, either in this country or on the continent, must often have seen, in protracted cases, the inconvenience to which the surgeon has been subjected, and the delay that has been caused by the assistant, from fatigue, becoming unable to afford the requisite support to the patient, behind whom he may have been placed; and a change has, therefore, become necessary. Not only this, but every spectator must also have seen the exhausted state of a patient increased by the close contact with his body of others placed by the surgeon to officiate as assistants. Thus, in cases of amputation in many of our public hospitals, I have often witnessed one assistant sitting behind the patient as a support, a second placed to hold or keep steady the healthy limb, a third and fourth to hold the arms, and a fifth to support the diseased member about to be removed; thus frequently increasing that exhaustion which it is not in their power to relieve. Added to which, when the operation is performed as a *spectacle* intended to convey instruction to pupils, as well as to afford relief to suffering humanity, these numerous assistants prevent many from seeing the different steps of the operation; of which, but from the situation the assistants occupy, a very good view might be obtained. Now although it is not intended, in the description of this operating table, to paint it as possessing any of the comforts of a down bed, still I am sure it will be found to answer the purpose for which it is intended better than any I have ever yet seen; and that it will also prove more calculated, from its construction, to mitigate the sufferings of those who are obliged to seek relief under the knife of the surgeon, than those tables in general use.

The table, of which the accompanying drawings, made by my friend, the Rev. Wm. Brown, afford a very good illustration, is made of oak. Its length is four feet, height two feet six inches, breadth two feet two inches; height of the back-board two feet one inch and a half. Both the table and back-board are covered with leather, beneath which there is a softish padding. On the upper margin, on each side of the table, is a plate of iron, with a channel or groove in it, along which the back-board

can be made to slide until it is at the part where the surgeon may wish to fix it. This is done by passing the iron pins through the holes in the side of the table, as shewn in the drawings. The back-board may be placed either perpendicular or to any degree of obliquity as the surgeon may choose, or the state of the patient require. This is effected by carrying the rack of the back-board backwards or forwards; and it is fixed by means of a screw in the holes on the inner side of the plate of iron, as may be seen in the drawings. The foot-piece, intended for the support of the healthy member, which may be fastened to the leg of the table by a silk handkerchief, can be moved higher or lower, according to the length of the limb; or this with the back-board can be removed altogether. The straps attached to the back-board can be used or not, according to the wish of the patient or surgeon. In cases of lithotomy or amputation, the advantages of a table of this description over those in general use must be obvious to every surgeon accustomed to perform any of the great operations in surgery. The support afforded by the back-board is more uniform and steady than that given by an assistant; the patient is also kept cooler during the operation than if reclining in the arms of another person; consequently he is less liable to faint,—a great and frequent cause of delay in all surgical operations of importance: the position of the body too can be varied with more regularity and precision. When the back-board is removed, the table of course may be used as any other; and from the strength and solidity of its make, it will be found particularly calculated for the support of patients during the use of the pullies in the reduction of dislocations.

I shall not dwell further on any advantages this table may possess, than by saying it has been examined by Sir Astley Cooper, who considers it by far the best constructed of any he has ever seen; and that it is owing to his recommendation I am induced to give it publicity.

It was made, at my suggestion, by a carpenter of this town of the name of Cother, who has received an order for a similar one from Mr. Weiss, of the Strand, whose well-known ingenuity will probably suggest to him some me-

chanical improvement in its construction. In the meantime, should any public institution think proper to order

one of Cother, I shall be happy to be the means of communicating their wishes to him. His price is six guineas.

SOMETHING "TANGIBLE."

To the Editor of the London Medical Gazette.

Sir,

As you will probably not deem it worth while to notice the forlorn attempt at a *jeu d'esprit* in the last number of the

Lancet, (a publication of which, from curiosity to be in at the death, I acknowledge myself to be one of the yet remaining readers,) permit me to call your attention to one peculiarity in the article alluded to. The respectable editor, while he is evidently smarting under the well-merited chastisement which you have recently inflicted on

him*, complains, nevertheless, that there is nothing "tangible" in your remarks. Nothing *tangible*, sir! why what is the plain fact? Wakley denounced a medical practitioner as an impostor, bringing nothing in proof of his charge but the weight of his own unsupported assertion, and the credit of his own professional reputation. The *Gazette* very properly tries Wakley's capacity to give or take away the character of medical men by the only recorded evidence which lets the profession and the public into the secret of his own practice and opportunities; viz. that given in the action which Wakley brought against the Hope Insurance Company, to recover money for losses alleged to have been sustained from the destruction of his house by arson. Since you directed attention to it, I have read the report of the trial in the *Times* of June 22, 1821, and I fully concur with you in thinking it most material that all medical men, whose professional reputation Wakley has attacked, or may hereafter seek to destroy, should peruse these details. You have, with the candour which is characteristic of your publication, abstained from entering into the nature of the evidence adduced by the Hope Insurance Company further than it bore upon the point strictly at issue, namely, the vindication of medical character, by the exposure of Wakley's professional inexperience, and consequent unfitness for the office he had assumed; and by contrasting them with his absurd pretensions, you have afforded such hints as enabled your readers to judge for themselves who was the impostor? It is this forbearance, I suppose, of which Wakley complains as affording him nothing *tangible*; but if he is capable of meeting your facts and inferences, why does he shrink from grappling with them? For my part, I have never seen an attack on a medical man's character answered in a way more *tangible* than that adopted in the *Gazette*, or which would have afforded an honest adversary a better opportunity to substantiate his charge, and thereby defend his own reputation, if he could.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum alt, dicendi periculum non recuso."—CICERO.

STATE OF THE MEDICAL PROFESSION.

A NEW medical year has commenced, and its dawn is brighter than that of several which have preceded it. The party who have so long and actively bestirred themselves to sow dissension among the various classes of the profession, are reduced to a number of individuals heretofore well and accurately described by Sallust, as the companions of Cataline, "all who were convicted of crimes or feared conviction—all who lived by perjury—all whom indigence or a guilty conscience disquieted—in a word, all the most necessitous and most daring;" or if we might venture to allude to Jewish history, we should find that they bear no small resemblance to the followers of King David, at the cave of Adullam, "and every one that was in distress, and every one that was in debt, and every one that was discontented."

Well as the system of detraction is now understood, and ill as it has sped, we shall still say a few words in explanation of the present views and avowed designs of the perturbators of our profession, strip them of their only remaining coverings, and expose them to the well-merited scorn of the public they have attempted to deceive, and the profession they are so anxious to degrade.

The startling notes most frequently repeated consist of abuse against the College of Surgeons, and the "certificate system." That some improvement in the laws of the medical corporate bodies is required from time to time, to meet

the necessary alterations in public education, and the increase of public wants, we have never denied; but we believe that such changes should be the result of great deliberation, and made by men well acquainted with the state of all classes of the medical profession. We want no medical constitutions like their political prototypes, the effect of a week's consideration, efficacious only to produce a violent reaction, and rivet still stronger by comparison the fetters of original error. That there is room for improvement we think, and have stated such to be our opinion in the earliest numbers of our journal, and we trust the Council of the College of Surgeons will set about it carefully and fearlessly. Let the friends of moderate reform persevere, notwithstanding their late discomfiture, and let all be open to reason from whatever quarter it may reach them, but unbiassed by clamour, unshaken by violence, and undisturbed by the reiterated abuse of the interested and the profligate.

The universal suffrage system, which would place the election to all offices of trust solely in the hands of demagogues, is almost too absurd to waste our readers' time in considering; and it is needless, for such a system never can, nor will exist. Granting the downfall of the present College (which we regard as altogether hypothetical), we appeal to the calm consideration of our readers, would the profession be benefited by the members of the late meetings at the Freemasons' Tavern being installed in its room? would the profession be honoured or regulated by such a body, heterogeneous in its materials, and although containing some men of talent, some who bid fair to arrive at those honours in their profession which many of the reviled council of the College deservedly possess, yet consisting principally of men who have nothing to lose, and every thing to gain, by such a

change? Is there any hope that moderate and desirable improvements will result from a system of continued and indiscriminate scurrility? Resistance naturally arises to unprovoked aggression, and a frame and temper of mind are produced least of all likely to cause enactments calculated to extend the benefit and raise the character of the profession. Look at the result when parliament last year was on the point of ameliorating the greatest evil in the profession—the law against dissection. When science might have been promoted, and the necessity obviated for shocking any longer public feeling and public decency, the party opposed the measure with all their endeavours, because it gave power to the College; the College, forgetting its importance, almost its necessity for humanity and for the largest and most desolate class—the poor—were content to refuse the boon which the legislature offered, because the entire control was not vested in themselves. These are the consequences, the fatal consequences, of such dissensions—strife, envy, inordinate love of power. Would it not have been better that the law should have passed, which set the anatomist free from legal reproof, and removed the brand from his forehead, but above all, which saved the poor and destitute from the fear of being murdered for their mortal tenement,—even with the *overwhelming* disadvantage of placing some control over its exercise in the hands of the Council of the College of Surgeons?

We quit this painful topic—painful to all who really love their profession—and proceed to the next favourite theme of those who would substitute self-instruction for labour, and anarchy for order.

The party object to the certificates of attendance on hospital practice and lectures, because they put money into the pockets of the medical officers of char-

ties; forgetting that, in this nation, money is the measure of successful talents in every class of the community. Neither Byron, the proud nobleman, nor Sir Walter Scott, the elegant scholar and accomplished gentleman, have scorned to derive money from their productions; and the large sums they have received prove the extensive delight which their writings have conferred. But, forsooth, the surgeon and the physician who teach must not receive any remuneration for communicating the knowledge they have acquired by years of laborious study. They alone must be accused of sordid meanness, for receiving an income in return for instruction, in a country where every one, from the highest to the lowest, turns his accomplishments, his science, or his labour, into gold.

Why?—because it suits the party to pander to the excited feelings of those who have been unsuccessful,—who have either grasped at more than they deserved, or who have wasted the time which should have been dedicated to improvement in dissipation—like Pierre to Jaffier, imputing the result of his follies and debaucheries to the oppression of the state.

The corporate bodies must legislate for the whole class over which they respectively preside; and, speaking generally, it is pretty certain men will not learn unless they are compelled to study. The certificate proves they have had the opportunity, and it ought not to be given if this opportunity has been neglected. It is the voucher that time has been spent in learning the art or science, and this is of more importance to the majority, and consequently to society, than the irregular coruscations of untaught genius.

In this respect, then, we think the Society of Apothecaries deserve well of the community. Their regulations, which come fully into operation this

year, are fraught with the greatest good to the numerous and important class over which they preside; and the apothecary who passes under the present system will not only be a man of great practical value to the largest portion of society, but have acquired the foundation of those sciences which, with after care, may rank him among men of the first consideration in the land.

We trust the two other corporate bodies will follow their example, especially in demanding certificates of a longer attendance on hospitals—we care not whether in London or the country. It is within the walls of hospitals, and in the chambers of the sick, that practical information is to be gained; and we hope to see the day when a certificate of two years' attendance on hospital practice will be the minimum required for members of the College of Surgeons, and double that time for those of the College of Physicians. An examination after such certificates (for men may have attended and not profited) would make every thing sure. An approximation to such a system exists: we trust it will be enlarged, and the public thus guaranteed against the impudent assumptions of men who profess to think all usefulness attained if they possess the name, without the accomplishments, knowledge, or practical science, which ought to belong to it.

We shall return to these subjects as often as our adversaries vapour about oppression and reform, and aim at their impudent attempts to entrap the discontented or unwary. We do not expect we shall be called upon frequently. Our endeavours to undeceive have been attended with complete success, nor shall we relax them even under the charge of being wearisome. Well may those who have sought by slander, detraction, and libel, to pervert the public taste, bring this charge against us. The wholesome aliment of the human frame is insipid

to those whose palate, vitiated by intemperance, can only relish those stimulative viands which make more manifest the loathsome diseases of their bodies; and we should have heard no charge of being wearisome if we had followed their example, and from time to time polluted our pages with false facts, scurrilous insinuations, and ribald jests, instead of overthrowing their arguments, denouncing their ignorance, and exposing their hypocrisy.

MEETING OF THE "BAT-CLUB."

FOR once in our lives we have to thank the Editor of the *Lancet* for a benefit, and, more wonderful still, for a politeness: a benefit in advertising our Journal in such a way as to shew how hard he is pressed by its success—and a politeness, in calling it by its right name. We allude to a squib in his last Number, giving a full and particular account of a meeting (which was never held) by what he calls the Bat-Club. What would the Editor of the *Lancet* not give that his statements were true—what would he not sacrifice, to get rid of this hated "excrecence," which has grown to such formidable dimensions? To speak professionally, what would he not do, could he but hope it would at length slough off, and leave him at rest, even though disfigured by the many scars which his ineffectual attempts at its extirpation have produced? He says it is "malignant:" alas! does he not know that such growths are not easy of removal, but increase most rapidly when fed by the corrupt juices of a broken, sinking, and vitiated system? Whether he be right in saying that the "excrecence" is of "malignant" character, we must leave it for others to decide: most people, we believe, think this is merely alleged by a disappointed individual, to account for its increasing size, which he has been unable to prevent, and can no longer conceal.

MIDDLESEX HOSPITAL.

ALTHOUGH the statement made by "John Middlesex," with regard to the attendance of pupils at Middlesex Hospital; is, as we stated, correct, yet his letter contains an important mistake:

instead of saying that the terms are lower than at "any other hospital," it ought to have been, lower than at "many other hospitals." The terms, in reality, are lower both at St. George's and the Westminster.

MR. KEY'S INTRODUCTORY LECTURE.

AN extraordinary scene took place at Guy's on Monday evening, when an attempt (the result of much previous preparation) was made to excite a clamour against Mr. Key. At present we shall only say, that the lecturer was received by his class in a manner which must have been as gratifying to his feelings as it was honourable to his pupils, and mortifying to the covert, *but not unknown*, instigators of the plot.

HOSPITAL REPORTS.

LA CHARITÉ.

Extirpation of the Uterus.

SINCE we reported, in a recent number, the case in which M. Recamier extirpated the uterus at the Hotel Dieu in Paris, this formidable operation has been performed by M. Roux twice—viz. on the 20th and 25th of September. The first of these cases occurred in private practice, and the latter in the hospital.

L—, aged 38, entered La Charité the 25th of August, labouring under an organic disease of the uterus. She had married at twenty-two, and had had five infants, the youngest being six years old. Four years ago she began to experience wandering pains about the uterus. These had become more acute during the last six months, and the patient had a very abundant bloody discharge; six weeks before her admission into the hospital the flow had been very considerable. The menses, for the first time, were absent at their proper period, the middle of September. Examination, per vaginam, had discovered a disorganization of the neck of the uterus, which was very hard, unequal, and with deep fissures; in addition to which the exploration detected a very considerable tumefaction of the body of the uterus—circumstances which were verified by several practitioners.

Sept. 25.—M. Roux performed the

operation in the presence of M. Boyer, MM. Lermnier, Fouquier, and Recamier, besides a great concourse of pupils and practitioners assembled in the theatre, a circumstance strongly censured by the reporter, who otherwise is favorable to M. Roux. The patient being placed as for the operation of lithotomy—first, the uterus was easily brought down as low as the vulva, by means of a pair of forceps; secondly, the vagina was divided, and the anterior surface of the uterus separated from the posterior surface of the bladder; thirdly, the perineum was opened; fourthly, the opening was enlarged at the sides with a probe-pointed bistoury; fifthly, either on account of the volume of the uterus, which was augmented, or from the shortness of the operator's finger, M. Roux had some difficulty, and occupied some time, in reaching the fundus, so as to divide the superior part of the ligaments; sixthly, the operator for a moment thought of increasing the depression of the uterus with Blundell's crochet, but he afterwards abandoned this idea. Seventhly, the upper part of the broad ligaments was divided. Eighthly, two ligatures were placed upon the lower part of the broad ligaments. Ninthly, the size of the body of the uterus preventing it from passing the entrance of the vagina, great delay took place in producing anteversion of the organ: M. Roux made many efforts, and M. Recamier, then assisting him, the uterus burst forth, covering the operators with blood. Tenthly, after the exit of the body of the uterus, the lower part of the broad ligaments was divided, as were the round ligaments, and the neck of the uterus was separated from the rectum. Eleventhly, on tightening the ligatures, that on the right side broke, and was not replaced. The operation lasted twenty-nine minutes.

The difficulty of effecting the anteversion of the uterus led some to think that the retroversion, after the manner of Blundell, would perhaps have been preferable.

The lips of the os uteri were tumified, nodulated, and separated by fissures, at the bottom of which the mucous membrane was already excoriated. The body of the uterus was about two inches and a quarter at its greatest breadth, and the length from the os uteri to the fundus exceeded four inches. The uterus was uniformly

hypertrophied, and its substance altered in colour and texture.

The patient, when she was removed to bed, was extremely pale, and her pulse concentrated; but little blood escaped by the wound. Compresses, dipped in cold water, were placed on abdomen and vulva, and were frequently renewed. Soon after there was some bleeding, but which (says the reporter) was much more calculated to prevent inflammation than to cause death;—nevertheless, the unfortunate patient did die. About ten o'clock at night extreme prostration came on, which lasted all night, and she sunk next morning, 24 hours after the operation.

The examination after death discovered a little blood in the pelvis, and some redness of the peritoneum at the same place, as if from imbibition. There was no distinct trace of actual inflammation: the bladder and rectum were perfectly entire. No other phenomenon worthy of remark, and nothing explanatory of the fatal result, was detected.—*La Clinique*.

Quere.—What were the symptoms in the above case which warranted the operation?—Ed. G.

GUY'S HOSPITAL.

Injury to the Knee-Joint—Amputation.

W. R. æt. 24, was admitted into Accident ward on Aug. 9, 1829, under the care of Mr. Key. He stated that about six months ago, when driving a cabriolet, the horse ran away, and coming in contact with a cart in Bermoudsey-Street, he was thrown out, and his knee struck forcibly against the curbstone. On rising, he ran after his horse for some distance, but finding his knee become stiff and painful, he came to the hospital. The knee was hot, painful, and much tumefied, but without any wound. Mr. Morgan, under whose care he was then admitted, directed leeches, cold lotion, and the diligent maintenance of the recumbent posture, under which treatment he recovered so as to be able to leave the house in about three weeks, with perfect motion and freedom from pain in the joint. He returned to his employment as a hackney-coachman, and in the performance of his duties was of course much exposed to cold and wet. In the month of May a tumor appeared above the knee, and he again applied to the hospital. It was necessary to open this tumor, and subsequently others, which allowed the exit

of considerable quantities of pus. Antiphlogistic measures were again pursued, and with similar good effects. He again resumed his employment for one or two months, but on August 9th was compelled once more to enter the hospital, under the care of Mr. Key. The opening which had been made above the joint, presented the usual fungatory edges of a fistulous sinus in such a situation, but from the absence of fever and constitutional disturbance, it seemed doubtful whether the joint was opened by ulceration. It was larger than natural, and slightly painful on pressure. He became much depressed in power, and the tendency to suppuration in the surrounding soft parts, increased. Under his great exhaustion, the matter burrowed, in spite of pressure and supporting diet, half way up the thigh, and also along the calf of the leg; and the powers of the constitution sinking, amputation was proposed, and performed by Mr. K. September 15th. It should be mentioned, that as soon as the matter began to burrow in the extensive manner shewn by the dissection of the limb, Mr. K. suspected the abscesses to be connected with the joint, and before the operation ascertained the fact by the introduction of a probe.

On inspecting the amputated limb, which was much tumefied, an opening with fungous edges was observed on the fibular side of the patella, which extended into the synovial cavity. By dividing the integuments of the ham, a large abscess was exposed, occupying the back of the leg. Ulceration had burrowed in the cellular membrane surrounding the gastrocnemius externus, thence between the superficial and deep layers of muscles round the head of the fibula, under the external head of the gastrocnemius internus, nearly extending to the commencement of the tendon of the gastrocnemii muscles downwards, and in front to the tibial side of the fibula.

In the thigh an abscess was found occupying the cellular tissue connecting the rectus and crureus muscles, which had communicated with the joint by a large opening situated between the tendons of the extensor muscles of the thigh and the femur.

Proceeding to examine the synovial cavity itself, its membrane was found exceedingly vascular, and so pulpy or villous as to have a granulated appearance. This was especially observable where the synovial membrane is reflected from the inner condyle of the femur to the edge of the tibia; and the condyles of the femur, where resting on the tibia, were extensively ulcerated, but without any defined edge; thus corroborating Mr. Key's remark, that the cartilage of joints is sometimes found chiefly diseased where opposed to the most vascular part of the inflamed capsule, as though the process of ulceration had been effected

by the membrane itself. That part of the cartilage covering the extremity of the femur, which is opposed to the patella, was most healthy. The cartilage of the patella was decidedly softer than natural. On the outer condyle, and exactly opposite the opening into the joint, there was a shelving depression, about three lines long, having a sharp defined edge. Ulceration had also extended its ravages to that part of the head of the tibia which is covered by the inner inter-articular cartilage. The ligamentocartilaginous structure was unusually small, and rather scabrous on its under surface.

The outer articular cartilage had, only in a very limited degree, partaken in the severe ravages of the disease which had been going on within the joint. Sinuous openings connected the abscesses in the back of the leg, in the thigh, and the joint severally.

Hypertrophy of the Mammaræ.

M. B. age 13½, light complexion, blue eyes, and of a more womanly aspect than her years would indicate, was admitted into Martha's ward on the 16th Sept. 1829, for a precocious enlargement of both mammaræ.

The following is the account she gives of the case:—About six months ago, being in good health, she felt a shooting pain in the breasts, which she observed then for the first time to be slightly enlarged and very hard. This hardness and pain decreased, but the breasts enlarged to the size of a child's head in the short space of about three months from that time, without any inconvenience having been experienced by her except that arising from their bulk. About a month after this she went to Sir A. Cooper, who gave her some aperient medicine, and applied pressure and bandages to the part. Under this treatment the enlargement seemed somewhat to subside, but not very much, and she is admitted here for the purpose of further treatment. Both breasts appear to be in a state of simple hypertrophy, with no disease of any importance evident. They are soft, and in every respect like those of a woman who has borne several children. Their bulk is the only source of inconvenience. They measure about 16 inches in circumference.

On the day (six months ago) when this enlargement commenced, she had a first appearance of the menses, which have since recurred at irregular intervals of four, five, and six weeks.

She states herself honestly to be free from all sexual inclinations; although the external organs of generation appear to be developed; and the account given by those who have known her, and watched her conduct, confirm the moral state of her feelings.

Since her admission, she has taken 5 grs.

of Pil. Ferri Co. twice a-day, to act on the uterus; has rubbed into the swellings about 3j. of Ungt. Potass. Hydriot. once a-day, and has supported them by bandages. They appear to be somewhat diminished in bulk from this treatment.

ST. THOMAS'S HOSPITAL.

Extensive Sloughing Sore on the Fore-arm.

JAMES SAILLITOR, twenty-four years of age, was admitted into King's Ward, under the care of Mr. Tyrrell, on the 11th of June; of rather pale complexion, and reduced in flesh, but has the appearance of having been rather a stout, fine young man. He states that, about a month previous to his admission, he was bled in the right arm, for some painful affection of the chest, attended with cough; that three days afterwards inflammation supervened, which quickly spread, and occupied nearly the whole of the extremity. Leeches were applied, and other means resorted to, but without effect; the part suppurated, and discharged a thin ichorous fluid, leaving a small wound at the middle of the back part of the fore-arm, which communicated with a subfascial sinus, and which, on examination with a probe, was found extending upwards nearly as far as the elbow, and downwards nearly as far as the wrist, in the latter direction insinuating between the extensor tendons, and becoming very deep. The introduction of the probe excited great pain and suffering for some considerable time afterwards.

Ordered to keep quiet, and take opening medicine occasionally.

13th.—Sinus laid open to its full extent upwards, and as far as was judged prudent, in the contrary direction; perhaps, in the whole, to the extent of six inches. When laid open, the integuments retracted considerably, laying bare some of the tendons, and exposing a surface of an oval shape, nearly the size of a small hand. The edges of the wound were drawn together slightly, by means of adhesive plaster, and a poultice of linseed meal put over the whole.

To keep his bed, and have a poultice applied.

14th.—Wound easy, and to all appearance doing well.

Cont. Cat. Lini, &c.

16th.—Dressings removed; upper part of the wound united; lower part surrounded by slight inflammation, and appears irritable. Complains of thirst. Pain in his back and head. Has once or twice had slight shiverings. Countenance flushed; tongue dry and furred, rather brown in the middle, and cracked; loss of appetite; restless; urine

high coloured: skin hot and dry; pulse quick, hard, and wiry.

Sumat. Haust. Effervescent. ʒij. Stia qq. horâ. Cont. Cat. Lini. Omit. Empl. Adhesiv.

17th.—Edges of the wound bearing an erysipelatous blush, which is diffused over the whole of the fore-arm and hand, and extending for some distance up the arm along the course of the absorbents. The wound itself has put on a sloughy appearance, and the upper part, previously united, has become opened; the integuments have again retracted, and given to the sore a very formidable aspect. Febrile symptoms very high.

Sumat Stat. Pil. Hyd. Sub. gr. vj. Cont. H. Effer. Stia qq. horâ. Sumat manè H. aperient. ʒij.

18th.—Constitutional symptoms have somewhat subsided. Inflammation of arm not so extensive. Wound now presents one continued slough, and appears even more extensive than yesterday.

Applic. Lot. Sol. Chl. Sod. p. j. ad p. iv. Cont. H. Effervescent.

20th.—Febrile symptoms have very materially abated. Wound more extensive, and presenting a very sloughy, irregular appearance, especially towards the edges. Here and there, over the surface of the sore, are observed small dark red bloody points. Surrounding inflammation still extensive.

Applic. Lot. Liq. Calcis c. Opio—Sumat. 6ta qq. horâ. Sulph. Quinin. gr. ij. Liq. Op. Sed. gtt. x. ex Infus. Rosæ. Sumat. omni noct. Hyd. c. Cret. gr. v.

23d.—Wound very extensive, occupying nearly the whole of the back of the fore-arm. Surface very irregular, and occasionally bleeding; edges of the wound very much elevated. Pulse quick, and rather wiry; thirst, &c. as before.

Applic. Sol. Sod. Chl. (undiluted).

24th.—Less pain in the wound. Inflammation not near so extensive.

Cont. Med. &c. Ordered a pint of porter daily.

25th.—Sloughs separating; edges not so much elevated; inflammation less diffused. Arm still painful up the course of the absorbents.

Cont. Lot. Sol. Chl. Sod. p. j. ad p. v.

29th.—Sloughs are completely removed, and the surface of the sore is granulating. Sleeps well at night. Thirst removed in a great measure. Appetite returning; bowels regular, &c.

Cont. Remed. Ordered a mutton-chop daily.

July 1st.—Wound presents a healthy granulating appearance; bleeds occasionally. Sleeps well. Enjoys his mutton-chop and porter.

Cont. remed.

4th.—Has been going on well, gradually gaining flesh, and recovering his former appearance. Granulations very painful. Ordered to be lightly strapped and rolled.

9th.—Wound nearly healed. Cont. remed. General health much improved. Went out on the 12th. Wound perfectly healed. Stiffness of the fingers, and inability to straighten them when flexed. Ordered to exercise his fingers as much as possible, and to use friction to the back part of the forearm.

Sept. 25.—We saw this patient at the hospital a few days ago, and found that he had recovered considerable power over the fingers, being able to straighten them all when flexed, excepting the middle one.

GLASGOW EYE INFIRMARY.

Traumatic Iritis.

JAMES FINLAY, æt. 21, was admitted on 3d June, 1879, by Mr. Mackenzie. Eight days ago the right eye was struck by a bit of iron, which brought on zonular redness of the sclerotic, discoloration of the iris, contraction and slight haziness of the pupil, dimness of sight, and circumorbital pain, so severe as entirely to prevent rest at night. Had twelve leeches around the eye, and the extract of belladonna applied. To take every night a pill, composed of gr. ij. of calomel, and one of opium.

6th.—Some whitish streaks visible in pupil, but thinks vision a little better. Pain relieved.

Vesicatorium pone aurem dextram.

9th.—Whitish streaks in pupil much less visible; pupil larger; bowels bound.

Sum. Sulph. Mag. 3j.

12th.—Cont Pil. Calomel. et Opii. Repetat. Sulph. Magn.

14th.—Redness abated, and pupil more dilated.

19th.—Still improves. Cont. Pil. 2nd q. q. nocte.

26th.—Almost the only remaining symptom is slight dimness of vision.

Instillatur in ocul. gtt. i. vini opii. Omit Pilula.

Sept. 11th.—Has continued perfectly well. Dismissed cured.

Traumatic Amaurosis.

David Wilson, æt. 10, 28th January, by

Mr. Mackenzie. About the 13th received a blow on the right eye from a boy's fist. On the 23d began to complain of loss of sight in that eye. The pupil moves but slowly; there is a haziness in the humours, and a slight degree of scleritis, marked by the usual zonular redness. Vision appears to be almost entirely gone. Occasional pain in the eye; no headache.

Hirudines xxiv. circum ocul. dext. Capiat. Pilulam Aloes et Hydrargyri. ter in dies. (Aloes, gr. ij. Hydr. gr. iij. in sing. pil.)

29th.—More scleritis, and more pain in the eye. Can distinguish the hand, a pen, and other objects, obscurely. Does not appear to see better, to the right or to the left, than looking directly forwards.

Vesicat. ad latus dextrum. Sum. Sulph. Mag. 3j. q. p.

Feb. 2d.—Scleritis continues. Considerable epiphora; iris a little granular. Mucous discharge well. Sight considerably improved, especially when he looks towards the left.

Cont. Pil. Al. et Hydr.

4th.—Scleritis less; vision improves.

14th.—Can read the whole of the infirmery card.

17th.—Right pupil a little irregular, but lively in its motions, and vision much improved.

23d.—Omitt. Pilula.

26th.—Gutta. Vini. Opii.

27th.—Knows very little difference between the eyes.

April 1st.—A slight musca volitans still appears before the right eye.

Sept. 12th.—Dismissed cured.

Exophthalmos, from Polypus in the Antrum Maxillare.

Feb. 2d, 1878.—James McCulloch, æt. 53.—The right nostril is occupied by a polypus. Cannot state exactly how long it has existed, but has had a feeling of stuffing in that nostril for some years. About six months ago was attacked by supra orbital pain, which darted towards the right side of the head. In a short time after he felt some pricking pain in the region of right antrum, stretching towards the inferior part of the eye, especially when he opened his mouth. This was followed by a swelling at the right side of the nose, which is gradually increasing. There is now exophthalmos to a considerable degree, in a direction forwards, outwards, and upwards. Has had diplopia for the last three weeks. Tears run over the cheek, and the eyelids adhere in the morning. Complains of a want of the sense of taste in the right side of the mouth. Want of sleep in the night, which he attributes to

the supra orbital pain. Pulse natural; bowels bound.

Capt. Olei. Ricini. ʒj. Capt. Tr. Iodinæ, gtt. xii. ter in die.

6th.—A . t. dos. ad gtt. xv.

10th.—Augent. dos. ad gtt. xx. Unguent. Hydr. Præc. Rubr. ad margin s palpebrarum.

18th.—It is discovered that the palate is yielding and elastic on the right side, under the antrum. A small ulcer is observed at the lower part of cornea of the protruded eye.

19th.—To-day the right nostril was cleared of that portion of the polypus contained in it; after which an opening was found between the nostril and antrum, sufficient to admit the end of the finger. The antrum was found completely stuffed with polypus of a medullary texture and white colour.

Omit. Tr. Iodinæ.

24th.—Mr. Mackenzie having made an incision through the integuments over the antrum, it was found that the fungus had produced absorption of the os maxillare, to the extent of half an inch in diameter. Through this opening the polypus was broken down and extracted. The os unguis was found destroyed, and the bony parietes of the antrum throughout diseased. A dossil of lint was introduced into the antrum through the incision. The bleeding stopped easily. The ulcer on the cornea was now cicatrized.

4th March —A profuse discharge of white fetid matter from the internal surface of the antrum. The nose and lachrymal region are much more natural, and the eye more in its place. The antrum was ordered to be injected daily with the following solution—

Rx Chlorid Calcis ʒj. Aquæ lbj. solve.

9th.—All pain had ceased; eye still more in its place; vision improves; and the shape of his face is much more natural. The discharge has lost its fetor, and is less in quantity. To continue the lint and the injection.

18th —Still improves; double vision gone.

27th April.—Very little discharge; vision improving.

Sumat. Pulv Carb. Ferri Præcip. ʒj. ter in dies.

Aug. 5th.—General health and local symptoms go on to improve. On pressing the lachrymal sac, thick white matter issues from the lower puncture, but is diminishing under the use of an injection of nitras argenti solution. The antrum seems contracting, and discharges very little. Water injected by the opening flows out by the nostril.

Sept. 24th, 1829.—M'Culloch still pre-

sents himself occasionally at the infirmary. He is in good health, and the vision perfect. The sense of taste has returned to the right side of the palate. The antrum is still kept open, and he wears in the opening a wooden style, having its head coloured black, so that it resembles a patch. On the whole, the deformity is not great, while it is evident that not only his eye but his life also has been saved by this well-timed operation.

WORCESTER INFIRMARY.

Empye a, with external Tumor.

THOMAS BOOTH, æt. 62, presented himself for admission at the Worcester Infirmary, and was received under the care of Mr. Sheppard, April 5, 1828, with an oblong tumor, about the size of the section of a turkey's egg, situated over the cartilages of the four inferior ribs on the right side, and about four inches below the mamma. The tumor is free from pain, of an irregular form, with a disk of inflammation on three of its most prominent points; it is firmly attached, and immoveable at its base; lobulated and knotty in its feel; somewhat elastic on pressure, and giving the sensation of a fluid in different cysts. He says, in the month of last September he fell on the edge of a hop-kiln, and struck the part severely; the blow, however, did not incapacitate him from going on with his work, that of hop drying; the pain soon abated, when, about two months after the blow, he discovered a small tumor, about the size of a large nut, which has continued to enlarge ever since: handling, at the present time, does not give any pain, and several enlarged vessels are apparent on the surface; to the eye and feel, it has some resemblance to the fungus hæmatodes. About three weeks since he was directed to keep it wet with a strong solution of salt, which he did for four days, and to this he attributes the first appearance of inflammation.

Tuesday, April 8th.—A puncture, with a lancet, was made in the middle of the tumor, when immediately a quantity of fetid pus gushed out, containing an innumerable quantity of hydatids, most of them about the size of small nuts. The integuments now collapsed, but on the patient being desired to cough, the tumor was immediately filled, and pus and hydatids spouted from the wound on every effort to cough; in all, about ten ounces of pus was discharged, filled with hydatids. A small dossil of lint was inserted into the wound, a poultice laid over it, and the man sent to bed.

9th.—He has passed a good night, and is this morning free from pain and fever, but has some tendency to cough: on renewing the poultice, a considerable quantity of the same fetid pus and hydatids were discharged from the wound.

10th.—Complains of pain in the neighbourhood of the wound, which discharges very freely; it is painful on pressure; his face is flushed; has had rigors during the night. Pulse 110; tongue white; cough urgent, with dyspnoea. Fourteen leeches were applied to the painful part, and his bowels were purged.

11th.—Pain and breathing greatly relieved. His bowels are open; tongue white; pulse 100; discharge from the wound very profuse; cough easier.

12th.—Has passed a good night, with refreshing sleep; pain and tenderness much better; pulse 80; discharge less this morning, but its character the same. He takes an inspiration without pain, but not without cough; tongue continues white; skin is rather hot. Twelve leeches were again applied; a bolus with five grains of calomel, and five of antimonial powder, was ordered to be taken directly, to be followed by half an ounce of castor oil, and to take a saline antimonial draught every four hours after the operation of the opening medicine.

On applying the stethoscope above the right nipple, the respiratory murmur was very distinct; below that part it could not be heard. On directing him to cough, the gurgling of fluid was heard in the chest; the left side appeared sound when examined by the same instrument.

14th.—The discharge is lessening; cough very troublesome, with copious expectoration.

16th.—Pulse 80; tongue cleaner; bowels open; has passed a good night; cough easier; expectoration continues; turns himself in bed with more ease; can rest on either side.

23d.—In all respects better; the discharge from the wound thinner, but more copious. He was allowed a little meat to-day, and ordered to have some porter daily.

26th.—He is going on well. The respiratory murmur now heard indistinctly below the right mamma. The discharge is lessening; the tongue is clean; he gets good nights; cough and expectoration much lessened.

June 28th.—He left the Infirmary much improved in his general health; cough was very slight, and the discharge reduced to the quantity of *Ziss*. in the 24 hours.

Booth presented himself at the Infirmary the beginning of June, in the present year. He returned to his labour more than six months since, and in the month of May he worked hard at his usual occupation, that of a woodman, in felling and barking trees. He considers himself in good health, and is able to do as much work as formerly. He has, occasionally, a little discharge from the wound; in all other respects is quite well.

* Midland Reporter.

NOTE FROM MR. WHITE.

To the Editor of the London Medical Gazette.

SIR,

In your Gazette of the 26th of last month, Mr. Costello, in his answer to Mr. Alcock's letter, has stated that he was to have been the bearer of recommendations to me from his friend in Paris, between whom and "Mr. White" a correspondence had been established, and that at length a patient had been procured. I beg to declare that in any correspondence I may have had with any person in Paris, the name of Mr. Costello was never mentioned, and that until some time after the arrival of that gentleman in England, I was not aware of his being in existence.

With respect also to the case to which an allusion has been made, and which appears, by Mr. Costello's account, to have been procured for him, I also declare that no such case was found for him, or any one else.

I am, Sir,

Your obedient servant,

ANTHONY WHITE.

Parliament-street, Oct. 6, 1839.

EPIGRAM.

*Chirurgus & Medico quo distat?—scilicet isto:
Enecat hic succis, enecat ille manū.
Carnifice hoc ambo tantum differre videntur,
Tardius hi faciunt, quod facit ille cito.*

TRANSLATION.

Distinct the Doctor from the Surgeon stands—
One slays with drugs, the other slays with hands:
Of both the only difference from *Jack Ketch* is,
They slowly do what he at once dispatches.

The above brings to our recollection the following satire on

A CONSULTATION.

A single Doctor like a skulker plies,
The patient lingers, and by inches dies;
But two physicians, like a pair of oars,
Waft him with swiftness to the Stygian shores.

ERRATA.

In our last number, page 23, for "*Ecclesiast*," read "*Ecclesia*;" and, page 32, in Baron Heurteloup's note, for "*Mr. Woltre*," read "*Mr. Wattie*."

LECTURES ON SURGERY,
Delivered at St. Bartholomew's Hospital,
BY WILLIAM LAWRENCE, F.R.S.

LECTURE III.—Oct. 5.

On the Nature and Classification of Diseases.

I ENDEAVOURED, gentlemen, in my last lecture, to give you a general notion of diseases;—I represented to you that they might be defined to be a deviation from the healthy or regular state of any solid or fluid of the body, or of any function; not, however, meaning thereby that the function could be disordered without a change in the condition of the organ that executed it. With regard to the question, whether fluids could be altered without some change in the solid parts of the body, I considered it to be hitherto undecided. I spoke to you of the difference between organic and functional diseases, regarding the former as comprehending all those cases in which some recognizable change after death is observed in the organization of the part, and arranging under the latter those instances in which no such change can be ascertained, but in which, however, we cannot entertain a doubt that a change must have occurred in the living condition of the part, as we cannot suppose that the function can be altered without some change in the state of the organ which is the cause of that function. I mentioned to you that I could not admit the notion of functional diseases, considered as independent of the organs by which they are exercised, as it seemed to me to involve the idea of an effect without a cause; and I farther held this notion to be objectionable, as leading to injurious practical consequences. This I attempted to illustrate from the views entertained respecting the nature of palsy, and the treatment adopted under the notion of that disease, consisting in a diminished, or reduced state of the nervous power of the part.

98.—v.

I alluded to some particulars in reference to the treatment of impaired vision; to the notion of debility in fevers, and to the idea of indigestion in affections of the stomach. I observed farther that I considered that all the organs of the body might be primarily diseased—that is, each organ may be disturbed by a cause which is applied to it in the execution of its peculiar functions; next, that all the organs may be secondarily diseased—that is, they may be diseased in consequence of derangement previously existing in some other part: these two kinds of disturbance being respectively called primary and secondary, idiopathic and sympathetic. I observed that the words sympathy and sympathetic did not explain how the phenomenon occurred, but that they merely pointed out the fact of the co existence of certain affections; that one part suffers with, or at the same time as another—this is precisely the meaning of the word sympathy.

I come next to speak of the difference in the nature of diseases. We have to determine not only what organ of the body is diseased, but also how it is affected; in what way it deviates from the healthy or regular state;—and this is a part of the subject which I am sorry to say is still involved in considerable obscurity. Our notions of the ways and modes in which the organs are disturbed, are hitherto imperfect. Probably there are many ways in which they may be affected, of which we have hitherto no idea.

In the great majority of cases, diseases depend upon increased action of the parts. We have to consider, in the first place, the original inflammation, and in the next place, the more or less considerable changes which inflammation, by its continuance and progress, is capable of producing in the structure of the parts. Now inflammations are not all of one kind, and there is one leading distinction which it is necessary to notice in adverting thus generally to the disease. Inflammation is

F

divided into *common* and *specific*: common inflammation is produced by an ordinary cause of disease acting on a healthy constitution. A wound, for instance, inflicted on a person in good health, will cause inflammation of a common kind and form. Other external agents would in the same way produce inflammation of a similar character. Specific diseases are those in which the constitution of the patient is unhealthy, the deviation from a state of health being either hereditary or acquired. Examples of this occur in scrofula, gout, and rheumatism, or in inflammation produced by one definite and specific cause, as in syphilis, small-pox, measles, scarlet fever, and contagious diseases generally: all these examples of disease can be produced by one particular cause, and by no other. Specific diseases, therefore, are peculiar in consequence of the constitution of the individual in whom the inflammation occurs, or in consequence of the nature of the cause applied. Now specific inflammation, thus excited, is nearly similar to inflammation that is excited by a common cause, at least the only difference consists in its modification; and frequently specific inflammation is so much like common inflammation, that difficulty is experienced in distinguishing the one from the other. We might often be unable, from the appearances, to distinguish between syphilitic bubo and enlarged glands in the groin caused by common inflammation.

Having heard that diseases generally consist in a state of increased action of the parts, you will naturally inquire whether there are not other classes of disease that arise from opposite causes—namely, diminished or reduced action of the parts; and you will probably have so frequently heard and read of debility, and of the means to be adopted to raise the powers of the system, that you perhaps think a considerable class of diseases are of this character. I believe we can hardly say any thing satisfactory or clear as to debility, considered as a *cause* of disease. It is true that debility is very frequently met with as a *consequence* of disease. The alterations that are produced by disease in a part render it more or less unfit for carrying on its functions. But we can in few instances recognize the state of debility in a part as the cause of disease, in the same way that we see a state of increased action to be the cause of those disturbances called inflammation. It is true, if cold be applied for a considerable time to a part it will reduce the action of that part, and the reduction may be carried to such an extent as ultimately to put a stop to vital action. The ossification of the arteries in the extremities of old persons seems, in a somewhat similar manner, to give rise to mortification in the extremity of the body. But the debility which we so frequently talk of

and read of is to be regarded as the effect of disease; and therefore it cannot be laid down as a general cause of disease. In considering the nature of diseases, debility is contradistinguished to increased action.

Many diseases produce a complete change in the organization of the part which they affect: these are called organic changes. In many instances they appear to convert the organ into a texture quite of a new kind, so that perhaps you see scarcely any trace of the original composition of the part itself. Examples of this occur in fungus hæmatodes, and in tubercles in various parts of the body, such as those which take place in the lungs. It often happens that the phenomena of these organic changes are assimilated, in a great measure, to those of inflammation—that is, with the increased action of the part, there will be a distention of the vessels; but this is by no means universal. Frequently changes of structure take place in a slow, insensible manner, and without the characteristics belonging to inflammation; so that we cannot refer them to the same kind of action. In cases of phthisis, depending on the formation of tubercles in the lungs, these often proceed till they occupy nearly the whole of the lungs, with very few symptoms that are perceptible.

The next general head is what we have already referred to—functional derangement. That is a kind of division which we merely take in consequence of our ignorance respecting the nature of many of these diseases. We see the function of a part deranged, and we lay it down as a head of disease, without understanding exactly what is the cause of the derangement. I believe you will find, that if you take any particular organ, and put together all that you can say respecting it under the several heads now mentioned, you will exhaust nearly all that can possibly be said about diseases. Suppose we take the eye, and consider, in the first place, the effects of a blow or injury of the organ; secondly, inflammation, divided into two heads, common and specific; thirdly, the consequences of inflammation; fourthly, the organic changes; fifthly, the functional derangement;—we shall find scarcely any thing that can be said about the diseases of the eye, that is not referable to one or other of these heads. However, as we may find some things that do not come under these, we constitute another head—sundries; and, in fact, in diseases of the eye, we have a manifest example, for cataract of the chrystalline lens cannot be referred to any of the heads that we have now mentioned. I think it better to adopt a division of this kind, because we do not thereby go beyond the extent of our knowledge; and when we look to matters referred to this division, we see in what

we are ignorant, and point them out as subjects of future investigation. I think it is better not to pretend to be informed upon a subject of which we have no knowledge. When we do not understand the nature of a disease, it is better to acknowledge the fact at once, and leave it for further investigation, rather than to take up an imaginary and theoretical opinion, and suppose that it accounts for appearances of which we are, in fact, ignorant.

When we have observed what is the state and nature of a disease, we are entitled to give it a name that is clear and expressive, and which shall at once indicate the disease itself. There are many diseases that are named in this way—thus cephalitis, iritis, gastritis, nephritis: these denote inflammation of the respective parts, the termination *itis* being chosen to designate the state of the organ, and the former part of the word the organ itself. These names indicate the particular kind of disease, gastritis—inflammation of the stomach, and all such names, expressing both the seat and the nature of the derangement. In a great many instances our knowledge is too imperfect to admit of diseases being named in this way, and then they are designated according to some particular circumstance that is clear to our observation: thus we have diarrhoea, dysentery, cholera. Frequently the circumstance according to which the disease is named is the change in the sensation of the part—for instance, gastrodynia,—pain in the stomach; or from discharge of some kind of fluid, as hæmoptysis, spitting of blood; hæmatemesis, vomiting of blood; diabetes, increased flow of urine, &c. All these pass in nosology as so many diseases; but, in point of fact, they are merely names of the symptoms of disease, and these names are to be considered as indicating the deficiency of our knowledge as to which organ is diseased. We should, of course, adopt the names that appear to denote the organic change; but being ignorant of this, we apply the name to some particular or leading symptom.

We come next to consider the arrangement, or classification of diseases; and this, in a subject so extensive and complicated as medicine, is a matter of very considerable consequence. I need not observe that in any subject in which a great number of parts are to be considered, the methodical distribution of these parts very much lessens the labour both of the learner and the teacher. If a person should at once take up the question of disease, and enter upon it without any kind of method, it would become overpowering. He would fall into a labyrinth, in which he would wander about without a guide. The variety of diseases is very great, and if you regard

their number merely, you might at the outset of your course despair of being able to understand such a multiplicity of different maladies.

The individual organs of the body are numerous, each of which is liable to be diseased in various ways; and every particular affection of an organ has its name, and is to be regarded, in point of fact, as a disease. Not only have all the various organs to be considered in this way as liable to disease, but in a great many instances a particular organ is made up of many component parts, and each component part is liable to a particular form of derangement; and all these derangements have received names, and appear in nosologies as diseases. Now take the case of the eye—I believe, in consequence of that part being open to external observation, and in consequence of its structure being complex, there are about 200 diseases, or rather more, enumerated by some nosologists as occurring in it alone; you must not, therefore, be surprised to find that when the diseases of the body are enumerated, they are reckoned up by thousands. The study of disease is not, however, such a complicated and endless subject as this view of the ample catalogue of names would lead you to expect. I mentioned to you in my introductory lecture, that although the individual organs of the body are numerous, the component tissues, or organic elements, of which it is built up, are few; in fact, the basis or ground-work of nearly all the organs of the body, consists of cellular membrane, blood-vessels, absorbents, and nerves. It is the various proportions in which this admixture is combined with some other structure less general, that make the difference of the various organs; hence, as the essential basis of the structure, or ground-work of the organs, is the same throughout, so the morbid affection must be similar. It is true that disease differs in the various organs of the body; but it is a difference of form, a difference of modification—its essential nature is nearly the same throughout.

That part of the science of medicine which considers names, and the distribution of diseases into classes, is technically called *Nosology*. Diseases have sometimes been considered topographically, that is, according to their situation in the body; and old writers have generally treated them in this way, beginning with diseases of the head, and descending to the other parts of the body. This, at all events, does not involve any technical ground of confusion—does not lead to error; it leads, however, to tediousness, because the various parts of the body are liable to similar affections, and if you describe them as they appear in each part, you must go over the ground

again and again. An abscess is the same whether it is formed in the head, the chest, or the limbs; and the same remark will apply to other affections. Medical nosologists have generally founded their arrangements on the nature of diseases, and their efforts have, in general, been very unsuccessful; because the nature of diseases, as I have already pointed out, is imperfectly known. Most of these nosologists have been but imperfectly acquainted with anatomy and physiology, and therefore their distinctions, so far as they go, have in most instances been fanciful, and have been founded on particular doctrines and symptoms, which will not bear examination; and, consequently, most of these persons, instead of rendering the subject clearer, will be found to have introduced mere names, which have left it more obscure.

Great advantage has been derived from arrangement in the study of natural history. A great man in the last century (Linnæus, of Sweden) employed himself in arranging all the productions of nature according to a certain method and order, in which he brought them together, so far as his knowledge extended, according to their natural affinities, and distinguished them according to their natural differences. The success which attended his efforts in natural history, led to the adoption of a similar method in the arrangement of diseases. A nosology was published by a French physician, (Sauvages) in which diseases were arranged in species and genera, and were combined in orders and classes, much in the same way that Linnæus arranged plants and animals, and other productions of nature. This arrangement of diseases by Sauvages included 10 classes, about 300 genera, and above 4000 species. The example of Sauvages was followed by others, and various systems of nosology were published, which I need not dwell upon at length, for they are now, as they deserve, nearly forgotten. Dr. Cullen, of Edinburgh, published a system of nosology, which was generally adopted, and is still maintained in this country; and which has sometimes been stated to be one of the best of the kind. Yet we find, upon examining it, that diseases are brought together which have no natural affinity; and that in many instances those are separated and put into different classes which resemble each other: so that if Cullen's nosology be the best arrangement of diseases, all that we can say is—bad is the best. Under the head of *Cachexiæ*, which is one of his classes, and which he defines to be depraved habit of body, he has the order *intumescentiæ*, or swelling; in which he has brought together *polysarcia*, excessive fatness; *pneumatosis*, distention of the chest with air; *tympanites*, distention of the intestines; *ascites*, dropsy of the

belly; *hydrocele*, distention of the scrotum with water! The diseases which are brought together under other orders will be found to be the worst possible examples of arrangement—equally unfortunate as that I have mentioned. Regarding this as one of the most successful examples of nosology, I think we may safely dismiss all of them from further consideration. I conceive it to be a sign of sounder ideas upon the subject that these systems of nosology have fallen into disuse, and that they have met pretty much with the contempt they deserve.

It is in vain to attempt to class diseases on the same principles that we follow in the arrangement of the productions of nature, because the two cases are by no means analogous. The species of natural objects are distinctly marked out by the hand of nature, and there can be no difficulty in placing them together. No one could confound the dog, the cat, the ox, the sheep, the lion, the tiger, and so forth; but when we come to examine into what are called the species of disease, we find that instead of being different, like those of animals, they run into each other by insensible gradations, so that it is extremely difficult to point out the distinctions between them. We are constantly meeting with effects of disease that are not describable in any form; and it is a common observation, that diseases which we meet with in nature are very little like those we read of in books. Thus the primary grounds of division are wanting in the nosological species of disease. Such primary distinctions are quite clear and definite in natural history; but they are altogether wanting, or are very obscure and indefinite, in disease. Then if we come to the division of genera, orders, and classes, the structure and economy of animals is well known, and hence leading circumstances can be adopted as the ground of separate division in their natural history. For example, a certain description of animal feeds on vegetables, and nutrition is conducted on a plan called *ruminating*, or chewing the cud;—another class feed on animal food, and they pursue a very different mode. Thus you have two natural classes in animals; those called *ruminating*, that chew the cud, and the *carnivorous*, or those that feed on their prey: and in reference to the economy of animals, the plan of their structure is arranged accordingly. You know, therefore, when you hear that the animal is referred to either of these classes, almost all the leading circumstances about its economy even before you are acquainted with the animal itself. If we could construct a nosology of diseases upon this plan, it would be of great assistance in teaching. If we could form classes founded on such well-known circumstances, it would lead to the study of diseases in regular order, and thus it would facilitate the labour of learning.

But when we look to the arrangement of Cullen—suppose we take tumors, we find put together aneurism, varix, ecchymoma, schirrus, cancer, bubo, sarcoma, warts and corns, &c.; in fact, he converts into a disease a tumor of a part without inflicting wound or injury—a pregnant uterus (a laugh). This is an arrangement founded upon elucidating things in a natural order. He has a head, *Dyalyses*—solution of continuity, under which you find *vulnus* a wound, *ulcus* an ulcer, *herpes* tetters, *psora* or itch; and the truth is, these are only examples of the kind of arrangement which is found throughout this celebrated system, and yet, strange as it is, I believe that in some institutions students are not eligible to be examined, touching their other qualifications, before they have been questioned as to their knowledge of Cullen's *Nosology*. Thus, it is required that a person should have his mind filled up with trash and rubbish. If real knowledge be acquired, it is very well, but it were much better to leave the mind empty than to fill it up with stuff of this kind.

Now, as diseases, for the most part, consist of changes in the state of the organs, the proper ground of distinction would be anatomy; at all events, it would be a ground of distinction that would not involve any error. There are two things to be considered in anatomy. There is the anatomy of form and position, and there is the anatomy of texture. The former is called descriptive, and the latter is called general anatomy. The latter, the anatomy of the texture, is that which shews the composition of the organs: it is a kind of analysis, reducing these into their constituent elements. A man of extraordinary genius, who lived in a neighbouring country, Bichât, and who died at the age of thirty-three, but left behind him a name that will live as long as the science he cultivated, in a work called "*Anatomie Générale*," has explained the anatomy of structure. He has reduced the organs of the body to their original component elements. He has, as far as it could be done, determined the nature of the constituent parts. He has shewn the proportions in which they enter into the organs of the body. He has subjected them to every kind of analysis, anatomical and chemical. In short, he has produced a work which is truly extraordinary, when you consider that it is the production of a man who died at so early an age—when you consider the novelty of his views, the great number of new facts he relates, the very clear manner in which he unfolds his doctrines, and the combinations which he has so beautifully traced. If we knew enough of the elementary or original organic structure of which the body is composed, we could then put down under that head all the va-

rious disturbances of each system, and thus we should have a natural arrangement of the diseases of the part—an arrangement grounded on anatomy. In considering diseases in this way, we should find that a great deal of time would be saved, because, while it explained generally the nature of the affection—the incidents to which original tissues were liable, we should only have in particular cases to point out the local circumstances which belonged to the affection of those parts. Suppose we take the cellular system. Inflammation of this is called phlegmon; proceeding to suppuration, it constitutes abscess. When the phenomena of phlegmon, consisting of inflammation and suppuration, have been once described generally, we need not repeat it in going over the various parts of the body; we should only have to notice in particular instances any local peculiarity. The same may be said of serous membrane, mucous membrane, and all other tissues. But we find it convenient in some cases to describe together diseases that affect particular parts, because it contributes to a clear understanding, and to distinguish from each other the various conditions of complicated organs. This, for example, is the reason of considering together the diseases of the eye.

The arrangement which we purpose to adopt in these lectures is founded on these two considerations; for the most part regarding diseases as occurring in the various organic systems of the body, but in some instances taking up disease as it is seated in particular organs. Although diseases are spoken of under single names, and therefore appear to the mind at first view as single objects, yet we find in general that each particular disease embraces a great variety of circumstances; and that in order to understand them thoroughly you must view them in a number of different lights. In the first place you survey those circumstances which denote the existence of disease, and which may be called generally the external signs of disease. You direct your attention to the circumstances under which the disease has arisen, and you investigate the occurrences that have taken place in particular instances. You next proceed to notice those changes in the state of the affected organ which produce any alteration recognizable by sense. This you can generally ascertain in external organs, and in many cases understand them in the internal organs. You ascertain the alteration in the state of the part first affected, and the alteration of its functions. You also observe the changes which may be produced either in the organs or functions secondarily. These circumstances are called the symptoms of disease—that is, the changes in the state of the part or of its functions which exist at the time you make

LECTURE 2 LECTURE ON SYMPTOMS.

in producing changes in the state of the organs, and they are called direct causes, or exciting causes. Thus, the application of heat to the skin produces inflammation. But what would produce inflammation of the skin without exciting it? There are called remote or disposing causes. Thus, a full meal of rich food, followed by indulgence in strong and stimulating liquors, is a disposing cause of apoplexy of the brain. A person in such a state is liable to have apoplexy if there is the application of certain exciting causes.

You will read much of what is called the proximate cause of disease—*proxima*. It means that which is immediately preceded the production of disease. Now you will observe that disease sometimes is actually traced to an altered condition of certain organs, and when our investigation of the subject is complete, we are able to do this. Therefore, the proximate cause in such cases is the circumstance that produced the altered condition of the organ. In other instances, where our knowledge of disease is imperfect, it relates merely to a certain resemblance of symptoms, and in such cases the altered condition of the organ, when found out, is considered to be the proximate cause of those symptoms. This is the sense in which the word is used by Dr. Cullen: his ideas turn on the symptoms that are exhibited in each case, and not on the changes that are to be observed in the organ: the proximate cause of Cullen is what we should call disease itself.

The division of causes will be best understood by stating a case to you. A certain individual has what is called a sanguineous temperament: he has a short neck, and a full habit of body, produced by indulgence in eating and drinking. This person makes a very hearty dinner or supper; he fills his stomach with food, he takes a considerable quantity of strong drink, and shortly afterwards he falls back in his chair, loses sensation, and has an attack of apoplexy. He either dies almost immediately, or without recovering his senses or voluntary motions, the internal movements...

in producing changes in the state of the organs, and they are called direct causes, or exciting causes. Thus, the application of heat to the skin produces inflammation. But what would produce inflammation of the skin without exciting it? There are called remote or disposing causes. Thus, a full meal of rich food, followed by indulgence in strong and stimulating liquors, is a disposing cause of apoplexy of the brain. A person in such a state is liable to have apoplexy if there is the application of certain exciting causes.

You will read much of what is called the proximate cause of disease—*proxima*. It means that which is immediately preceded the production of disease. In other instances, where our knowledge of disease is imperfect, it relates merely to a certain resemblance of symptoms, and in such cases the altered condition of the organ, when found out, is considered to be the proximate cause of those symptoms. This is the sense in which the word is used by Dr. Cullen: his ideas turn on the symptoms that are exhibited in each case, and not on the changes that are to be observed in the organ: the proximate cause of Cullen is what we should call disease itself.

The division of causes will be best understood by stating a case to you. A certain individual has what is called a sanguineous temperament: he has a short neck, and a full habit of body, produced by indulgence in eating and drinking. This person makes a very hearty dinner or supper; he fills his stomach with food, he takes a considerable quantity of strong drink, and shortly afterwards he falls back in his chair, loses sensation, and has an attack of apoplexy. He either dies almost immediately, or without recovering his senses or voluntary motions, the internal movements...

partaken would be called by nosologists the occasional cause of the disease. The sanguineous temperament, short neck, and fulness of habit, are the predisposing or remote causes. Thus you perceive that in investigating the mode in which disease is produced, you have often got a series of changes to observe; each of which, in reference to that gone before, and to that which follows, is successively effect and cause.

Having then observed the nature of the case, having noted the existing symptoms, and traced the cause;—having watched the course and progress of the disease, and its termination, we complete our investigation of the subject by opening the body of the patient after death, in case death should occur. This leads us to find out the changes which have been produced in the state of the part immediately affected, or of others connected with it. By dissection we ascertain what may be called the *pathological* condition of every part. The knowledge of this is of great importance towards enabling us to determine the seat and nature of disease. This inquiry into the changes which take place in the organs after death has materially contributed to give us just and correct notions respecting the nature of diseases;—it has dispelled all those fanciful views in which disease was attributed to certain alterations of the fluids, and of the condition of the vital properties; for it has shewn us in most of these that material changes have been produced on the organs diseased. This examination completes the history of disease. In many cases we do not find a change produced in the organ, but even this negative circumstance is of use in detecting error.

Now, important as this examination is, and valuable as is the knowledge which it imparts, you must not consider that it is a matter of the *first* importance. In investigating the nature of diseases, the point of chief consequence is *CLINICAL OBSERVATION*—that is, the ascertaining of all those changes which take place in the state of the organs, or in the condition of the functions, during life. The examination after death completes the history of the case; but it is of subordinate consequence, compared with clinical observation during life. By mere observation we can understand a great deal of the history, origin, causes, progress, and terminations of disease, without examining the bodies at all. It often happens that the nature of disease cannot be ascertained by examination after death; for, in many instances, the patient does not die under its influence, and in others we are not allowed to make the examination; and where we are permitted to do so, we can frequently detect no change. Therefore you will observe that the cases are comparatively few in which direct information can be obtained; and although, in

these, the knowledge is of a very important kind, yet the general doctrine of treatment, and the general mode of curing diseases, have been discovered by experience and observation during life, and not by the discoveries resulting from examination after death. I mention these circumstances to you that, although you may take every opportunity of following that kind of investigation which pathology institutes, you may not entertain an exaggerated notion of it; but may estimate that part, as well as others, exclusively by its real value.

When we examine the symptoms of disease—when we pay particular attention to the changes produced in the condition of the affected part (the primary or local changes)—we are led to distinguish diseases from others that resemble them; we are led to distinguish the diseases of particular organs from those of contiguous parts. The particular act by which we discriminate diseases is the *diagnosis*; the particular sign on which we dwell in making the distinction, is the diagnostic sign: in general, it is the primary or local symptom existing in a part that marks the seat of disease, and that constitutes the diagnosis.

When you are called to investigate the seat of disease, you find the patient and his friends extremely anxious: you find a great desire existing to know whether he will recover, or whether he is likely to die; whether he will recover completely or only imperfectly; how long the disease will last; when he will be able to go about, and resume his occupations. These inquiries are really very natural, and, although you may find them sometimes troublesome, I hope you will be inclined to answer them readily and with kindness. You must make allowances for the anxiety of friends on these occasions, and should not suffer yourselves to be betrayed into any thing like hastiness, or an expression of dissatisfaction. This is, in fact, a point of policy, as well as of good feeling. Few persons can estimate professional knowledge and skill, but all are able to estimate and to value attention and kindness. When you compare the state of the patient as it is under your immediate observation, with all that you know from other sources respecting the nature, progress, termination of disease, and effects of treatment in particular cases, you are then able to prognosticate, or predict, the course and event of the disease in such case. This constitutes what is called *prognosis*; a point of great practical importance.

Having observed the disease in the way I have mentioned, you naturally pass to the consideration of the means by which the disease may be arrested, or may be conducted, through a certain course, to a successful termination. These means fall under three divisions—namely, the management of ex-

the observation. The word symptom means happening with—occurring together; therefore symptoms of disease must be something which you actually see or observe at the time of examining the individual case. The word sign of disease is more comprehensive, because it embraces all the circumstances that have taken place prior to the time of examination. Now the symptoms of disease found in this way are divided into the primary—that is, those changes which occur in the state of the part itself; and secondary, or those that occur in the condition of other organs. Increased redness, swelling, and yellow discharge, are primary symptoms of clap. Increased frequency of making water, or a swelling of the testicles, are secondary symptoms of the same disorder. In looking to the symptoms of disease, practical persons have particularly turned their attention to the discovery of such as would constantly take place in each particular disease, and these have been called *Pathognomonic* symptoms, the meaning of which is, symptoms pointing out individual diseases. Secondary symptoms, for example, cannot be pathognomonic. Even with respect to symptoms that belong to the organs immediately affected, you do not always find them the same. Thus, symptoms may be present, or they may be wanting; so that few come under the description of what may be truly called pathognomonic. These are mostly found in external disease, and are referable to what we ascertain by surgical examination. Thus, for example, if the patient have pain in making water, and the water is interrupted in its passage from the bladder, or if he feel pain on the motion of a carriage, or any other motion of the body, we suspect that he has got a stone in the bladder. But all these symptoms may exist in consequence of other diseases besides stone. If, however, we introduce a metallic instrument into the bladder, and by striking against something it makes a noise there, it is a pathognomonic symptom of stone.

Symptoms have been divided into *local* and *general*: local symptoms are those existing in a part; general symptoms those changes effected on various or several parts. Hence those are called general which take place in conjunction with several different primary affections. The symptoms constituting fever may occur with local inflammation, and also with injuries: they may take place in connexion with numerous other conditions, and therefore do not point out particularly the nature of any disease.

In the investigation of disease we next come to look at the circumstances by which the affection is produced—that is, we examine into the *cause*, which, as you will readily conceive, is a very important part of the inquiry. Some causes act immediately

in producing changes in the state of the organs, and they are called direct, immediate, or *exciting* causes; thus, the application of hot water to the skin produces inflammation. But other causes produce a state of body in which disease is likely to occur without actually giving rise to it. These are called *remote* or *predisposing* causes. Thus, a full state of habit, produced by indulgence in eating and drinking, is a predisposing cause of apoplexy or palsy. A person in such a state is likely to have apoplexy or palsy on the application of certain exciting causes.

You will read much of what is called the proximate cause of disease—*causa proxima*; it means that which has immediately preceded the production of disease. Now you will observe that disease sometimes is actually traced to an altered condition of certain organs, and when our investigation of the subject is complete, we are able to do this. Therefore, the proximate cause in such cases is the circumstance that produced the altered condition of the organ. In other instances, where our knowledge of disease is imperfect, it relates merely to a certain assemblage of symptoms; and in such cases the altered condition of the organ, when found out, is considered to be the proximate cause of those symptoms. This is the sense in which the word is used by Dr. Cullen: his ideas turn on the symptoms that are exhibited in each case, and not on the changes that are to be observed in the organ; the proximate cause of Cullen is what we should call disease itself.

The division of causes will be best understood by stating a case to you. A certain individual has what is called a sanguineous temperament: he has a short neck, and a full habit of body, produced by indulgence in eating and drinking. This person makes a very hearty dinner or supper; he fills his stomach with food; he takes a considerable quantity of strong drink, and shortly after such a feat he falls back in his chair, loses sensation, and has an attack of apoplexy. He either dies almost immediately, or without recovering his senses or voluntary motion, the internal movements of the body are carried on one, two, or three days, and then he dies. On examining the body you find a considerable effusion of blood into the substance of some part of the brain. Now in this case, if you regarded the loss of sensation and voluntary motion as the disease, the pressure on the brain by the effusion of blood is the proximate cause of it. If, however, you regarded this circumstance merely as a symptom, then the effusion of blood, and the pressure on the brain, would be diseases themselves, while the proximate cause would be the excitement of the circulation produced by repletion; and the hearty meal of which such an individual has

partaken would be called by nosologists the occasional cause of the disease. The sanguineous temperament, short neck, and fulness of habit, are the predisposing or remote causes. Thus you perceive that in investigating the mode in which disease is produced, you have often got a series of changes to observe; each of which, in reference to that gone before, and to that which follows, is successively effect and cause.

Having then observed the nature of the case, having noted the existing symptoms, and traced the cause;—having watched the course and progress of the disease, and its termination, we complete our investigation of the subject by opening the body of the patient after death, in case death should occur. This leads us to find out the changes which have been produced in the state of the part immediately affected, or of others connected with it. By dissection we ascertain what may be called the *pathological* condition of every part. The knowledge of this is of great importance towards enabling us to determine the seat and nature of disease. This inquiry into the changes which take place in the organs after death has materially contributed to give us just and correct notions respecting the nature of diseases;—it has dispelled all those fanciful views in which disease was attributed to certain alterations of the fluids, and of the condition of the vital properties; for it has shewn us in most of these that material changes have been produced on the organs diseased. This examination completes the history of disease. In many cases we do not find a change produced in the organ, but even this negative circumstance is of use in detecting error.

Now, important as this examination is, and valuable as is the knowledge which it imparts, you must not consider that it is a matter of the first importance. In investigating the nature of diseases, the point of chief consequence is *CLINICAL OBSERVATION*—that is, the ascertaining of all those changes which take place in the state of the organs, or in the condition of the functions, during life. The examination after death completes the history of the case; but it is of subordinate consequence, compared with clinical observation during life. By mere observation we can understand a great deal of the history, origin, causes, progress, and terminations of disease, without examining the bodies at all. It often happens that the nature of disease cannot be ascertained by examination after death; for, in many instances, the patient does not die under its influence, and in others we are not allowed to make the examination; and where we are permitted to do so, we can frequently detect no change. Therefore you will observe that the cases are comparatively few in which direct information can be obtained; and although, in

these, the knowledge is of a very important kind, yet the general doctrine of treatment, and the general mode of curing diseases, have been discovered by experience and observation during life, and not by the discoveries resulting from examination after death. I mention these circumstances to you that, although you may take every opportunity of following that kind of investigation which pathology institutes, you may not entertain an exaggerated notion of it; but may estimate that part, as well as others, exclusively by its real value.

When we examine the symptoms of disease—when we pay particular attention to the changes produced in the condition of the affected part (the primary or local changes)—we are led to distinguish diseases from others that resemble them; we are led to distinguish the diseases of particular organs from those of contiguous parts. The particular act by which we discriminate diseases is the *diagnosis*; the particular sign on which we dwell in making the distinction, is the diagnostic sign: in general, it is the primary or local symptom existing in a part that marks the seat of disease, and that constitutes the diagnosis.

When you are called to investigate the seat of disease, you find the patient and his friends extremely anxious: you find a great desire existing to know whether he will recover, or whether he is likely to die; whether he will recover completely or only imperfectly; how long the disease will last; when he will be able to go about, and resume his occupations. These inquiries are really very natural, and, although you may find them sometimes troublesome, I hope you will be inclined to answer them readily and with kindness. You must make allowances for the anxiety of friends on these occasions, and should not suffer yourselves to be betrayed into any thing like hastiness, or an expression of dissatisfaction. This is, in fact, a point of policy, as well as of good feeling. Few persons can estimate professional knowledge and skill, but all are able to estimate and to value attention and kindness. When you compare the state of the patient as it is under your immediate observation, with all that you know from other sources respecting the nature, progress, termination of disease, and effects of treatment in particular cases, you are then able to prognosticate, or predict, the course and event of the disease in such case. This constitutes what is called *prognosis*; a point of great practical importance.

Having observed the disease in the way I have mentioned, you naturally pass to the consideration of the means by which the disease may be arrested, or may be conducted, through a certain course, to a successful termination. These means fall under three divisions—namely, the management of ex-

ternal influences, which tend to the restoration of health, such as diet, air, exercise, clothing, sleeping, walking, &c. which are called by the name *dietetic*; the second, *pharmaceutical*—the application of internal and external remedies depending upon a knowledge of *materia medica*, and of the changes the diseased organs undergo; the third, *chirurgical*—operations or other manual proceedings: so that you observe surgery is a part of therapeutics, or treatment. The various circumstances connected with disease that I have just mentioned, taken altogether, constitute the science of *pathology*; and the investigation of disease is not complete till you have surveyed it under all these aspects, or varieties. This shews that these subjects have a material bearing upon each other, and your views would be very imperfect unless you surveyed the whole of them. It has sometimes happened that disease has been considered in one or other of these views only, and particular treatises have been written upon them. Such partial views of the subject have been given under especial names: the consideration of nomenclature constitutes *nomenclology*; the consideration of symptoms, *symptomatology*; of causes, *etiology*, &c.;—and there have even been treatises on the art of *diagnosis*. I cannot approve of any of these partial views of disease. It is so necessary to contemplate the subject altogether, and the various parts elucidate each other so materially, that we ought not to attempt to take any particular view, but to consider the whole in conjunction.

I have mentioned to you an observation made respecting the nature of diseases—namely, that in a great majority of cases it consisted in *inflammation*. In point of fact, in giving a course of medical or surgical lectures, we are principally occupied in describing inflammation, and pointing out the mode of treating it. I therefore think that we should begin with this important subject. I have mentioned to you, that the arrangement of diseases I shall adopt will be founded on the different component tissues of the body; but I think it necessary, first, to describe inflammation and treatment as connected with it. It is of particular importance, in a surgical course, in which we have to describe the nature of injuries, and their effects; for these are only modifications of inflammation. You will find that in doing this we shall save both time and trouble. In the subsequent portions of the course we shall have occasion, in describing the tissues, to advert to the general principles laid down on this part of the subject;—I shall, therefore, in my next lecture, call your attention to—
INFLAMMATION.

CLINICAL LECTURE

ON THE

OPERATION OF LARYNGOTOMY.

By CHARLES BELL, Esq.

Surgeon of the Middlesex Hospital, and Professor of Surgery in the University of London.

GENTLEMEN,

AT no time does the duty of the surgeon appear more important than when he comes into the midst of a distressed family, one of whom is in danger of immediate death from suffocation; for the suddenness of the attack, the agony of the sufferer, and the real danger to life, are apt to agitate him at a time when he must be calm, decided, and dexterous. Before I read the case to you, I shall put certain preparations into your hands, to which I must refer in explanation.

[The lecturer here handed round the preparations, showing the natural structure of the larynx, and gave a short description of the anatomy of this part. He then drew attention to the peculiar sensibility residing in the glottis.]

This sensibility of the glottis calls into action the whole class of respiratory muscles. It is placed here for the purpose of guarding the entrance of the lungs; and if the smallest husk, or crumb of bread, alight upon this part, there is an immediate spasm, extending through all these muscles, to expel the foreign body. But just in the same manner that this extensive class is roused into action, those little muscles which move the arytenoid cartilages and the *cordæ vocales*, contract spasmodically. Whenever any thing foreign touches the highly-irritable spot in the glottis, these muscles shut up the narrow slit of the *rima glottidis*, and cause the sensation of suffocation. In such a case, therefore, as the present, when a foreign body is lodged in the windpipe, we have to observe that there is, at first, a sudden spasm, or fit of suffocation: after a time, this painful struggle relaxes; but it returns, and this return of the difficult breathing marks that the obstruction is spasmodic, and not mechanical.

In the course of the attack, these fits recur at shorter intervals—they become more frequent, though apparently less

violent; and you will observe how they are attended with flushing and turgescence of the face, with a blood-shot eye, great anxiety and struggling. But by-and-by a change takes place—there is now no struggle, nor any effort to avoid suffocation—there is no longer that animated and terrified look; but, on the contrary, the patient lies still: instead of the suffused face, his cheek is pale and cold, and his hand feels clammy. Had the obstruction been altogether mechanical, the effects would be uniform; but being, as I have said, spasmodic, there is a deceptive appearance of improvement from diminished irritability. Seeing this change in his condition, his attendants think that he is relieved, and in the way of doing well; when, in truth, his case is desperate. These new symptoms arise from effusion taking place in the lungs. The difficulty experienced of drawing the breath through the narrow glottis, and the violent mechanical play of the lungs, bring on effusion into the extremities of the bronchiæ, or into the common cellular texture of the lungs; and of this, the pale leucophlegmatic countenance is the sign.

Thus, when the patient dies, the immediate cause of death is the state of the lungs; the remote cause is the spasm in the glottis. The inference which you are to draw from this is, that if you do not decide at the first what is to be done, but defer operating, there is danger of being too late: you may perform the operation, and remove the foreign body, but the patient will die from the effusion into the lungs.

Case of Foreign Body in the Trachea.

Sept. 1.—Mary Waters, æt. 9, was admitted into the hospital at nine o'clock this morning, with symptoms of suffocation. The report given by the friends was, that yesterday afternoon, being in school, and eating a plum, the child laughed, and was reprimanded by the mistress, who gave her at the same time a slight tap on the cheek; at that moment the child was sensible that the plum-stone had got into her throat. She was immediately seized with a difficulty of breathing, which has continued, with occasional severe attacks, ever since. A probang was passed into the œsophagus, and an emetic was given to her, before she came into the hospital.

It was evident that she required immediate relief. Mr. Bell said that he slipped, unobserved, to her bed-side, so as not to disturb or frighten her, for the purpose of examining her manner of breathing. She lay with her head raised high; she was restless, shifting her position, and tossing her arms; her chest rose high, and her nostrils were dilated; the sound of her breathing was hissing, husky, and impeded—it was in sudden gasps.

Having collected what tubes, probes, and forceps were likely to be of use, the child was laid on pillows, placed on the table so that her position was inclined, not horizontal. This was done for two reasons—because a person breathes with difficulty in the horizontal posture; and, because it permits the blood in the wound to flow outwards.

An incision was made through the integuments an inch and a half in length, the centre being opposite to the cricoid cartilage. The thyroid and guttural veins were seen turgid: it was not possible to avoid them, and they bled freely. Continuing the dissection on the fore part of the trachea, a small artery, the thyroidea anastomotica, was divided, and the wound bled considerably, so that the incision into the larynx was delayed a few minutes. The point of the scalpel was then thrust into the membranous space between the cricoid and thyroid cartilages. The child did not appear at all relieved, or only in a very slight degree, by this opening.

“My disappointment was now considerable. When I had done this operation before, the relief was immediate: no sooner had the point of the knife penetrated the membrane than the harsh sawing sound of the voice ceased, and the air came *siffling* through the wound; and when the end of the scalpel was used to hold apart the sides of the slit, and a quantity of mucus was discharged, the breathing was composed and easy.”

The probe was passed upwards through the glottis into the pharynx, but nothing foreign was found interrupting the passage. The probe was then passed from the wound in the larynx down into the trachea, with every precaution, lest the foreign body might be thrust downwards by it; but nothing was to be discovered there. At this time the breathing was worse; the child's colour was darker, and a degree of insensibility

prevailed. A portion of a large gum catheter was passed down into the trachea, and retained there, and the child's face and neck were bathed with cold water. The breathing became sensibly easier, and the freshness of colour returned to the cheeks and lips. The tube being withdrawn, further attempts were made to discover the stone, but without avail. Mr. Bell at this time thought of putting the child to bed, but, resolved to leave nothing undone, he explored the passage once more. He felt the pharynx with his finger introduced into the mouth. He then passed the catheter by the wound through the chink of the glottis, and examined the sacculi laryngis; he then sounded deep into the trachea; and now he thought he could feel a roughness more than belonged to the cartilages. He, therefore, enlarged the incision downwards, and having bent the end of a probe so as to make a little hook, he passed it down into the trachea: by means of this, he succeeded in catching the edge of the stone, and brought it to be visible in the wound; then, with the small dressing forceps, he extracted it. It was half of the stone of a plum, and it had lain with its rough convex surface towards the concavity of the tube.

Immediately after the stone was withdrawn, the child opened its eyes and looked about, apparently with the conviction that the thing was accomplished. Nothing could be more striking, during the whole of the operation, than that a child so young should have so perfect a notion of the necessity of something being done for its relief, and that it should remain so submissive.

The wound was dressed superficially, and the child was put to bed, breathing freely—to the great delight of those present, for it had been abundantly apparent that it was an affair of life or death.

Evening.—The child is perfectly quiet, and has slept a great deal.

Sept. 2d.—She is remarkably well; she speaks low, and complains of hunger. She breathes at present with perfect ease, and has done so ever since the operation. Leeches have been applied to the neck, and she has had some laxative medicine.

Sept. 12th.—The child is running about, and is quite well; but the wound is still open, and the granulations pro-

jecting. The zinc lotion is ordered, with compression by adhesive strapping.

Sept. 22d.—The wound is healed. Mr. Bell said, that the father, with the child in his hand, came running after him as he left the hospital to return thanks. When he said to the father, "I am distressed that the child has not recovered its voice:" he replied, "It was only her shyness; she speaks as well as ever she did in her life."

It is first to be remarked, gentlemen, that in this, as in former operations, it was the surprise of every one how deep the trachea and larynx lay in the wound. It is this which makes the operation difficult; the more so, that from dissecting the dead body, you are not led to expect it.

It is said in this case that I passed the probe upwards. The reason of doing this is, that foreign bodies are apt to be caught in the chink of the glottis, and it is necessary to push them up into the pharynx. But, indeed, I ought to have considered that in such a case the symptoms are more severe than those exhibited in the present. I passed the probe downwards in the absolute certainty of finding the foreign body there. I shall here shew you how the surgeon may make a fatal error. A child was brought into the hospital some years ago in a state of suffocation, as it was said, from having drawn a pebble into its windpipe. The house-surgeon, seeing there was no time for delay, made an incision between the thyroid and cricoid cartilages, and he then passed a probe from this part up into the throat. Thinking he could do no more, he desisted. The child died: and on examining the part, it was found, on slitting up the trachea, that the stone was impacted not a quarter of an inch below the incision. If he had turned his probe down, he would have touched the stone, and the child would have lived.

A case lately occurred in Dublin to a surgeon whose reputation has extended so as to make him well known to us here, which was attended with some curious circumstances. A boy had rubbed down a plum-stone in its centre, so as to open its cavity, and make a whistle of it. While practising upon this whistle, it suddenly slipped into his wind-pipe. He could breathe, notwithstanding, without much difficulty, although he had occasional paroxysms

of suffocation. Several days had elapsed before he presented himself at the hospital. To satisfy those around him that the stone was still in his windpipe, the boy began to whistle, of his own accord, upon his instrument. Without puckering his lips at all, he could produce a very clear whistle by merely throwing out the breath from his chest. With this evidence, the surgeon made an incision into the trachea; and when he had pushed a catheter through the chink of the glottis into the mouth, the boy called out that he felt the stone, and had swallowed it. Three days afterwards, however, he was again heard whistling as before. The breathing had continued impeded; and it was found also, by the use of the stethoscope and percussion on the chest, that the lungs on one side did not expand in breathing. It was inferred that the foreign body was probably still lodged in the trachea, and that it might be covering one of the divisions of the bronchial tubes. The incision in the trachea was therefore enlarged a little downwards, and the stone was expelled shortly afterwards during a fit of coughing.

In illustration of this fact, that a foreign body may be expelled by coughing, you will find some very interesting experiments performed upon dogs by M. Favier, as quoted by Sabbatier. He popped a foreign body into the glottis at the moment of inspiration. The animal was immediately convulsed, and it was thought he must have died, but he became so quiet that they deferred the further part of their operation for six hours. They then opened the trachea by dividing three of the cartilages, when the body was immediately forced out. The experiment was ten times repeated with a nail, a ball of lead, &c.; and although these were pushed deep with instruments, the body was cast out the moment that the incision was made. These experiments were performed to oppose the opinion which declared the operation of bronchotomy to be precarious from the difficulty of discovering the body.

The most important part of a clinical lecture, gentlemen, is the confessions of the surgeon. I ought in this case to have determined in my own mind where the foreign body lay, for you will observe that the symptoms are different according as the body lies in the grasp of the glottis or in the trachea. I might have known that if it had been in

the sacculus laryngis, for example, the symptoms would have been more violent, and the danger more pressing.

In the case operated upon by the house-surgeon, the mother came running in with the child in her arms, just after the pebble was swallowed, and in twenty minutes the child was dead. In the present instance the stone lodged lower down, and the child you have seen survived during the night. But do not delay performing the operation after you have ascertained that a foreign body is in the windpipe, because the child may be suffocated in the instant by the body rising from the depth of the windpipe, and being caught in the glottis. Thus a child, after drawing a cherry-stone into its windpipe, was nearly choked, but suddenly got relief; and some time after, while playing on the carpet, it was seized with another fit of suffocation, and died. The cherry-stone was found in the sacculus laryngis; and there can be no doubt that in the period between the two attacks, the cherry-stone had lodged deep in the windpipe, but that during the gambols of the child it had fallen forwards into the larynx.

In Pelletan's Clinique Chirurgicale you will see a case where the surgeon performed bronchotomy on a child, and extracted a bean. The weakness of the child after the operation was such that they believed him dead; but he recovered, called on his parents, and cried to have his playthings, and yet this boy died in fourteen hours. Another boy had the operation performed, and died in consequence. The expression is strong—"le coup mortel était porté:" although he lived for two months. Now the fatal termination in these cases was attributed to a gorging of the brain; and there is no doubt that a long-continued struggle for breath affects the circulation in the head in a very remarkable manner. But it affects the lungs more directly and more violently. When a person dies from suffocation, owing to some disease of the throat, the lungs do not freely collapse on examining the body. Here, then, there is a proof that they have suffered, and to this danger I call your attention particularly. But let us in future be alive also to the observation of Pelletan, of what takes place in the brain.

For some time after this operation I was very anxious for the child's life,

and I shall state the reason of this anxiety. A woman was brought into the hospital, who, in her frenzy, had plunged a penknife into her throat. It pierced the upper part of the thyroid cartilage, and entered at the union of the *cordæ vocales*. She was suffocated at the end of some months by the granulations which filled up the passage of the glottis. Another young woman, attempting to destroy herself, drew a penknife down the fore part of her throat—not in the vulgar way of cutting it across. She thrust the knife into the trachea, and divided five rings of the tube. She survived the first effects, but was suffocated by the retraction of the cut edges of the cartilages, and the swelling of the inner membrane, which thereby diminished the capacity of the tube. You see, therefore, the source of my anxiety. When we saw the granulations spring out from this wound, it was natural to apprehend that such granulations might also sprout inwards. With regard to the possibility of the divided cartilages retracting, the manner in which I operated might possibly prevent this; for you will observe that my first incision was made through the membranous space between the thyroid and cricoid cartilages; and when I enlarged it, I cut through the cricoid cartilage. Now you mark the peculiarity of this cartilage—that it is a complete circle, and that, when divided, its edges will resume their place, being supported by the continuity of the hoop on the back part. The cartilages below, that is the cartilages of the trachea, are not complete hoops, or rings; and therefore, when divided into two lateral portions, they may be displaced and retracted more easily. However, I must not omit saying that the windpipe has been divided with this perpendicular incision, without being followed with the consequences which I have apprehended, and which I have myself witnessed. I have recommended to my young friends to make experiments to illustrate this subject.

The last observation I shall make is less practical; but still it is very curious in a physiological point of view. When the probe was passed upwards, the child coughed, and expressed uneasiness, which shewed that the chink and the parts above the chink of the glottis were much more sensible than where we were operating.

It was also remarked that, although

no sensibility was evinced on putting the probe downwards into the trachea, yet, when it was passed so far within the tube as to touch the bifurcation, coughing and indications of superior sensibility were produced—as in touching the larynx.

ANALYSES & NOTICES OF BOOKS.

“ L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

An Essay on the Use of the Nitrate of Silver, in the Cure of Inflammation, Wounds, and Ulcers. By JOHN HIGGINBOTTOM, Nottingham, Member of the Royal College of Surgeons of London. Second edition, much improved and enlarged. 1829.

WHEN a practitioner takes a particular remedy under his especial protection, the result is generally favourable to medical science, because the frequency of its employment in his hands soon leads to a discovery of what it will, and what it will not perform. It is true that we must generally receive the testimony of the patron with some degree of limitation, because those who look with a partial eye will often see more than reaches the duller optics of the indifferent spectator; but even with this drawback, it seldom happens that a series of experiments with any particular remedy, by an intelligent and candid man, do not lead to a juster estimate of its real powers.

The nitrate of silver has been for some time a deserving *protégé* of Mr. Higginbottom, of Nottingham; and the various applications which he appears to us satisfactorily to have shewn may be made of this substance, constitute no unimportant addition to practical surgery. The principal use heretofore made of the nitrate of silver, as a local application, has been for the purposes of an escharotic, as indeed the familiar name *lunar caustic* sufficiently implies; but according to our author, this action is very subordinate to the power of the remedy in subduing inflammation, whether of the phlegmonous or erysipelatous character—preventing suppuration in the former case, and arresting the extension of the disease in the latter.

Sometimes this object is attained by merely blackening the cuticle with the caustic, in which case a chemical union takes place between it and the animal texture. In other instances it is requisite to produce vesication, which is said to have "a singular and peculiar effect in subduing the process of inflammation;" while with regard to suppuration, it would appear to be sometimes prevented, and at others modified, so that the pus is reabsorbed or rendered thinner, and escapes by a smaller orifice than in similar cases where the silver has not been used.

Such is a very general statement of the positions advanced by Mr. Higginbottom, which he considers to be new, and we believe with justice—at least we never met with them thus expressly laid down in any author previously to the appearance of the first edition of the work before us.

The mode of applying the nitrate of silver for the various purposes above mentioned, consists in washing the part with soap and water, so as to remove any oleagenous matters from the surface, which is then to be wiped dry. The inflamed part and the skin immediately round it is afterwards to be moistened, and a long stick of the nitrate of silver passed along the surface, so as to touch every part, not only of the inflamed skin, but of the surface all round it, to the extent of an inch or more. In slight cases, it is sufficient to pass it once over the surface; but in severer injuries this must be done twice, three times, or oftener, if it be desired to produce rapid vesication, or if the cuticle be thick, as on the palm of the hand or sole of the foot. The part is to be exposed to the air till it dries, and is to be kept cool.

If the application has been properly made, the inflammation will generally be found to have subsided in 24 hours; but if there be any spot which has escaped being touched, the patient will complain of it, and such part must now have the caustic passed over it. There is generally more or less of vesication at this time. Within three days there is more vesication, but less swelling, while the pain is generally almost gone. The parts feel "puffy," and are free from inflammation. The vesications ought to be left to form crusts undisturbed, and these should be suffered to remain till they drop off of themselves.

So far the effects attributed to the

nitrate of silver may be characterized as negative—consisting in arresting inflammation; but Mr. Higginbottom has also found that results of a more positive kind may be obtained from it. He thinks that, under particular circumstances, it "modifies the action of the parts, so as to induce that form of inflammation which Mr. Hunter has termed the adhesive." Thus in simple incised wounds union by the first intention is frequently effected, by passing the nitrate over the surrounding cuticle; or if the wound be punctured, suppuration is prevented. In bruises where, from the severity of injury inflicted on the parts, sloughing would otherwise inevitably follow, the nitrate of silver, timely applied, preserves the continuity of texture, and averts the death of the part. The adhesive inflammation is not less certainly induced by this remedy in certain forms of ulceration; but this application of the lunar caustic is familiar: we mean the general principle of applying it to certain kinds of ulcers—not that it has been used precisely as directed by Mr. Higginbottom.

Another mode of employing the nitrate of silver is by producing eschar. An eschar may be adherent or unadherent; if it can be persuaded to adhere, the wound beneath "infallibly" heals. To form the necessary covering to a wound or ulcer, the remedy must be applied not only to the open surface, but also to the surrounding skin; for the eschar, in drying, contracts, and would thus, otherwise, leave part of the wound uncovered. Care must be taken then to leave the eschar undisturbed; but as it separates at the edges, from the part below healing, these ought to be pared off with a pair of fine scissors. A good method of securing the preservation of the eschar is to moisten the surrounding skin, and apply gold-beaters' skin over it. This method is said to render all dressings and ointments unnecessary, saving much suffering to the patient, and labour to the practitioner. But sometimes the eschar is unadherent, and this depends upon the formation of matter, or of a scab beneath: if from the former, it may be discovered in 24 hours, by making a little puncture, in the centre of the eschar, with any sharp instrument, and pressing out the pus; the nitrate of silver is then to be applied to the orifice thus made, or the same may be done at the edge where the

fluid oozes out. If from any accident the eschar be entirely separated before the healing is complete, the nitrate of silver must be applied *de novo*. If the eschar does not separate favourably, the formation of a scab beneath may be suspected. If there be pain and inflammation, with no appearance of healing, a cold poultice must be applied for some days, by which the eschar is removed, and afterwards the silver is to be applied as before.

The degree of pain which immediately results from applying nitrate of silver, of course varies. In small wounds it is trifling, but in recent wounds of all kinds it is proportionably more severe than in ulcers. The pain, however, is transitory, and the actual amount of suffering less than by any other mode of treatment.

When there is no chance of forming an eschar, owing to the size or situation of the wound, the cure may often be effected by applying nitrate of silver, and then a poultice, and repeating these from day to day; till at length the time arrives when the case admits of the formation of an adherent eschar, and thus healing up the part. This method is particularly recommended in neglected punctured wounds, and in cases of recently-opened abscesses.

The author, after the general statement, of which we have above given an analysis, proceeds to illustrate his mode of treatment in different forms of inflammation, wound, and ulcer. We shall make such selections from these as may be necessary to put our readers fully in possession of the subject.

Phlegmonous Inflammation.—"CASE 1. Miss —, aged 21, of gross habit, was seized on Saturday with acute pain across the patella, whilst sitting at dinner, without any previous known cause. On walking a short distance she found that she was lame, and that her knee was stiff. Half an hour afterwards the knee was observed to be swelled, but there was no redness. A poultice was applied. In a few hours more, inflammation was observed to be spreading up the thigh; the poultice was taken off, and soap liniment was applied.

"On the following morning the poultice was applied, and it was continued all day, and until Monday, when I saw her. The inflammation had spread along a third part of the length of the thigh, and downwards, nearly to the ankle;

the limb was much swollen, exceedingly hot, and a slight fluctuation was felt just below the patella. I applied the nitrate of silver over the whole surface of the inflamed parts, and did not open the abscess, as I knew from experience that the tumor would subside rather than increase soon after the application of this remedy. I directed an emetic and purgative medicine, and desired a fracture-cradle to be put over the limb, which was kept exposed.

"On Tuesday the inflammation was quite arrested, and there was no heat. I opened the abscess below the knee with a lancet, and some fluid was evacuated, which had more a serous than a purulent appearance. I applied the nitrate of silver within the cavity of the abscess.

"On the following day there was an increase of inflammation below the escharred part, on the foot, attended with swelling. I applied the nitrate of silver on that part, and directed an opening medicine. On the next day all inflammation was gone, but the limb was still much swollen.

"On the succeeding Monday the swelling of the limb had much subsided, and there was very little complaint. I directed a repetition of the opening medicine. On Wednesday the patient was convalescent. The leg required a bandage till the swelling was gone."

Whitlow.—It seldom happens in this affection that the patient applies till suppuration has already taken place. The plan recommended by our author is then to open the abscess freely, apply the nitrate well within the cavity, and envelope the whole in a cold poultice.

Erysipelas.—When this attacks the face slightly, the nitrate of silver is not recommended till the usual constitutional measures have been tried without success; but in several severe cases the progress of the inflammation has appeared to be arrested, and the same opinion is expressed by Dr. Storer, in a letter to the author, which he has inserted in corroboration of his own views. We confess, however, that the evidence of the nitrate of silver, applied to erysipelas of the face and head, appears to us the least satisfactory part of the volume. The mode of using it consists in its application upon, and for some way beyond, the inflamed surface; of course the usual constitutional means are not to be neglected.

Inflammation of the Absorbents.—
 “Mrs. H. aged 34, had a swelling similar to a boil on the fore arm, near the wrist, the centre of which had a vesicular appearance; and on removing the loose skin, presented an ulcerated surface, with highly inflamed and irregular edges. The absorbents were inflamed on the inside of the fore arm, nearly to the axilla. Mrs. H. could assign no cause for this affection, which had been coming on for four or five days. She complained of feeling indisposed and feverish.

“The nitrate of silver was applied to the ulcer, slightly over the surrounding inflammation, along the course of the inflamed absorbents, and on the surrounding skin, wherever there was any swelling. A blue pill, and infusion of senna and salts, were administered.

“On the following day the inflammation was observed to be completely checked. The patient stated that in about half an hour after the application of the nitrate of silver, she experienced sensible amendment, and that the arm became much cooler and easier; and that it had remained so during the night.

“On the second morning there were increased heat of the parts to which the nitrate of silver had been applied, and slight vesications on the parts which had been before most inflamed, viz. along the course of the absorbents, and around the ulcerated surface.

“On the third day there was vesication nearly all over the parts which were previously inflamed; but on the fourth day it had disappeared, and the cuticle was peeling off, leaving the parts free from inflammation. The eschar was adherent over the ulcer.

“On the fifth day there was a slight discharge from underneath the eschar, which continued for several days; afterwards the eschar remained perfectly adherent, and from this time no further attention was required.”

Punctured wounds are often of the most formidable description, and in no case is the beneficial influence of the nitrate of silver more conspicuous. If, in such an injury, there be any loose portion of skin at the orifice, it is to be cut away in the first place; the puncture and surrounding skin are then to be moistened with water, and the lunar caustic applied within the puncture

(but not very deep) and to the surrounding skin to the extent of an inch, or more, if the swelling extend farther. The eschar will frequently remain persistent, and the case require no farther care. If, however, some time has elapsed since the receipt of the injury, and the orifice be nearly closed by the swelling, a little pressure is to be employed, so as to squeeze out any fluid that may be in the wound, after which the nitrate of silver is to be applied, as in the former case. If abscess be found, it must first be freely opened, and treated as in whitlow. This mode of treatment, by means of nitrate of silver, is said to be particularly useful in wounds from needles, nails, hooks, saws, &c. in the stings of insects, and in inflamed leech bites. The author adds, that, during the last seven years, he has had frequent opportunities of treating wounds received in dissection by these means, and that he has “the most perfect confidence in their success.” The following is a case of formidable wound of the throat healed in this way.

“———, aged 50, in returning home in the dark, in a state of intoxication, fell on one of the spikes of the iron palisades at his door. It pierced between the os hyoides and the chin, to the depth of nearly an inch. The wound bled a little, and was very painful when I saw him some hours after the accident. The aperture was rather large and gaping, and, as there was no possible chance of healing it by eschar, I applied the nitrate of silver on the surrounding skin, to the extent of several inches, and to the edges of the wound. I then brought the edges of the orifices together by means of straps and adhesive plaister, and afterwards applied a compress and bandage. I prescribed a purgative.

In six days, during which interval there had succeeded no inflammation or swelling, and scarcely any pain, I removed these dressings. The wound was much closed, and a serous discharge flowed from it. I applied the nitrate of silver again on the exposed surface of the wound, then a little lint with the neutral ointment, then sticking plaister, and lastly a compress.

“In three days more the wound was nearly healed; there was rather more fulness round the puncture, but no in-

inflammation. The nitrate of silver, lint, and ointment, were again applied. At the next visit of this patient, three days afterwards, the wound was well.

"In this case the application of the nitrate of silver prevented the inflammation of the surrounding integuments, and the wound healed without the unpleasant effects frequently consequent upon large punctured wounds."

Bruised Wounds.—When he has been applied to sufficiently early, our author has always succeeded in preventing the process of sloughing. The following illustrates the mode of applying the silver in these injuries.

"Mr. Granger, aged 36, received a severe bruise, by a quantity of stones which had been piled up falling upon the outside of the leg. He was extricated from this situation with much difficulty. Besides the bruise, the skin was removed from the outside of the leg to the extent of ten or twelve inches in length, and in some parts to that of an inch and a half in breadth; and in the fore part of the ankle a deep furrow was made by the rough edge of one of the stones. I applied the nitrate of silver about half an hour after the accident, over the whole surface of the wounds, and protected the eschar by the gold-beaters' skin. The patient was directed to keep the leg cool and exposed to the air. He took no medicine. On the succeeding day the leg was a little swelled, but the patient did not complain of any acute pain, but only of a sense of stiffness. An adherent and perfect eschar was found to be formed over the whole extent of the wound. There was no fever.

"On the third day the swelling had abated. No further remedy was applied. The patient was still enjoined rest. On the fourth day the swelling was nearly gone. The eschar remained adherent. The patient walked about. From this time the patient pursued his avocation of a stone-mason: no further remedy was required, no inconvenience experienced, and the eschar separated in about a month.

"I think it totally impossible to have cured this wound by any other remedy in less than a month, during which period the patient must have suffered much from pain and fever, and have been quite confined to the bed or sofa. It is also quite certain, I think, that

there would have been an extensive slough, from the severity of the bruise. This was doubtless prevented by the application of the nitrate of silver."

Ulcers, except when small, cannot be successfully treated by an attempt to form an eschar. In large ulcers, attended with inflammation, Mr. Higginbottom directs the patient to take some opening medicine, and apply a common bread and water poultice for twenty-four hours. The inflamed parts are then to be washed with soap and water, and dried. Having moistened them with plain water, a long stick of the caustic is to be applied all over the inflamed and ulcerated parts twice, and rather more freely on the ulcer itself. Lint is then to be put on this, and the whole inflamed parts covered with linen, spread with neutral ointment. A compress of five or six folds, and a common roller, complete the dressing. At the end of four days the ulcer is to be examined, when the inflammation will be found nearly or entirely gone. The silver is then to be applied to the ulcer as before, and this method repeated every three or four days, till the cure be completed. The patient may walk about after the first or second application of the remedy.

Burns and Scalds.—By passing the lunar caustic once slightly over a burnt surface, the pain is increased for a short time, but afterwards entirely subsides, and the blackened cuticle peels off in a few days, leaving the part well. When the cuticle has been removed, the application as above produces an adherent eschar, and thus prevents ulceration. When a slough already covers the surface, our author has removed this with the scissors and forceps, and afterwards applied the nitrate of silver. He has not, however, he informs us, had an opportunity of using it in very extensive recent burns. After having applied it once, as above directed, he covers the parts most severely burnt with lint, and the whole with neutral ointment spread on lint.

Several cases are given; of these we select the following, in which a hard and painful cicatrix followed a burn.

"Timothy Coleman, aged 32, whilst in a state of intoxication, burnt his shoulder and arm very extensively. He was under the care of a surgeon, and the sore was healed in ten weeks. There

still, however, remained an inflamed surface, larger than the size of the hand, over the deltoid muscle. It had the appearance of fungus cicatrized over; it was attended with so much heat and pain as to prevent him from sleeping at night, or following his employment in the day for thirteen weeks, even after it was said to be cured. He had used a number of remedies. His health continued good.

"I first saw him on June the 20th, 1827. I applied the nitrate of silver as in external inflammation, over the whole diseased surface. I directed the part to be exposed to the air for three days, and then to be covered with the neutral ointment.

"As my patient resided at a distance in the country, I did not see him again for a fortnight, when he informed me that eight hours after the application of the nitrate of silver, he had more ease than he had experienced since the accident, that he was nearly free from pain, and slept well.

"I again applied the nitrate of silver very freely on the whole affected surface, as there still remained several inflamed spots, besides several slight ulcerations caused by the nitrate of silver. I then covered the part with the neutral ointment.

"In another week I saw my patient again. He said he had suffered more from the last application than from the former one; that it had acted more like a blister; that there had been a free discharge; and that the eschar had separated sooner. There appeared, however, scarcely any irritation, except from a few superficial ulcerations, on which I passed the nitrate of silver very lightly: I continued the neutral ointment. A few weeks afterwards this man called on me to say that he was quite well.

"This peculiar case is almost incurable by any other means."

In an appendix are contained several cases illustrating the use of the nitrate of silver as a blister, in various morbid affections, particularly of the knee, and in inflammation of the urethra; as well as its application to numerous other injuries, as gun-shot wounds, &c. &c.; but we have already made our readers acquainted with the general views entertained by Mr. Higginbottom, and his own ingenuity will suggest their application to individual cases.

The work contains several letters from respectable practitioners who have adopted this method of treatment with success, and we think the body of evidence before us clearly proves its utility.*

CASE OF MRS. DENMARK.

To the Editor of the London Medical Gazette.

October 12th.

SIR,

THE following letter was addressed to the Editor of the *Lancet* a fortnight ago, and considering his abhorrence of all "hole and corner proceedings," I can imagine no reason for his having declined to publish it. It would be unjust to Mr. Wardrop to suppose that the friendship of the *Lancet* is particularly inflicted upon him, and yet it is very certain that if Mr. Brodie, Mr. Earle, Mr. Guthrie, or Mr. B. Cooper, had, in a similar manner, examined a disease, the appearances of which were to overthrow or to confirm their peculiar doctrines, the Editor of the *Lancet* would most bitterly, and, I confess, I think very properly, have reproached them for thus deviating from the established custom of the profession.

I am, Sir,

Your obedient servant,
A FRIEND TO SCIENCE.

To the Editor of the Lancet.

SIR,

ONE of the leading principles by which you profess to be influenced, is to discountenance and openly reprehend concealment of every kind, upon subjects which the profession have a right to expect will be thrown open to them in the most candid manner. I, therefore, address you upon the subject of the late Mrs. Denmark's case, which has excited so high a degree of interest in this and foreign countries. The evidence that has yet been adduced by Mr. Wardrop, for the purpose of justifying the operation of applying the ligature on the distal side of an aneurismal tumor, has been deemed by the most competent judges to be inconclusive and unsatisfactory. It has for some time been known, that Mrs. Denmark's disease was rapidly proceeding to a fatal termination, and, of course,

* Some trials of this remedy have been made at St. Bartholomew's Hospital, see page 94.

a great and very laudable desire was felt by every scientific surgeon to be accurately informed of the appearances detected on dissection, as they would, to a certain extent, corroborate or weaken the hypothetical doctrines maintained by Mr. Wardrop. Under these circumstances, sir, it was but natural to imagine that that gentleman would be most anxious to make the dissection as public as possible;—that he would most studiously avoid the appearance or possibility of partially judging the merits of his own case. But Mr. Wardrop, who, upon most occasions, is a sufficiently sharp-sighted man, was injudicious enough to conduct this very important examination in a secret manner, for no persons were present but himself and an assistant. Mr. Wardrop, of course, had previously made up his mind as to the appearances he hoped to find, and we all know how easy it is to fancy that which we earnestly wish to detect. I will not impute to Mr. Wardrop discreditable intentions, but I must declare him to be a most improper judge of this case. His enthusiasm leads him to view every circumstance connected with the subject to which it belongs partially, if not erroneously. As a proof of this, I have only to refer to the assertion he makes in your number for Sept. 19th, that “the soundness of his principles has not only been recognised by the distinguished surgeons of this country, but by those of the continent also.” Mr. Wardrop, sir, grossly deceives himself: His principles have not been recognised.

It is the liberal and proper custom of the profession for every practitioner to solicit the attendance of some friend and competent judge to witness dissections from which important information is expected, and, if ever there were a case which ought to have been examined as publicly as possible, it was that of Mrs. Denmark.

The preparation, we are told, is to be placed in the museum of the College of Surgeons. But the great object was to ascertain the appearance of the disease *in situ*, before it was disturbed by removal. However fairly and properly the morbid parts may be prepared, the evidence that must result from their inspection now will be very unsatisfactory, in comparison with that which ought to have been afforded. With a singular want of delicacy, he has con-

stituted himself the sole juror in his own cause, and he must not be surprised if the favourable verdict he has returned be regarded with an eye of suspicion.

I am, Sir,
Your obedient servant,
A FRIEND TO SCIENCE.

CASE OF SCHIRROUS DISEASE OF THE STOMACH.

To the Editor of the London Medical Gazette.

SIR,

I beg to present you with the following case of schirrous disease of the stomach, and shall be obliged by your insertion of it in an early number of your Gazette, if you deem it of sufficient importance to merit publication. I have not added any observations upon the case, as was originally my intention, its details being in themselves somewhat extended.

I am, Sir,

Yours, &c.

RICHARD MIDDLEMORE,
M.R.C.S. &c.

Birmingham, Sept. 19, 1829.

Edward Harrison, æt. 43, applied to me on the 20th of May, 1829, for relief under the following circumstances:—He had (he said) been subject for many years past to occasional pain at the stomach, particularly after having taken an unusually hearty meal, or after sitting, as his business sometimes required him to do, in the bent position for a long space of time; latterly, the pain had been more frequent in occurrence, the appetite had diminished, and he had occasional nausea and flatulence; but, notwithstanding this list of ailments, he looked as if he were in good health, and was certainly in the enjoyment of full muscular power: he also told me, that he had never been intoxicated in the course of his life, and had even been ridiculed for his rigid sobriety. I made a somewhat hasty examination of the case, and prescribed some aperient medicines for immediate use, requesting him to call upon me in a few days, when I had intended to have investigated his case more attentively; but, instead of doing so, he took other advice, and applied in succession to three or four practitioners, whose medicines,

however, were as little successful as my own.

At this period, about eight months from the time of his first consulting me, he placed himself under the care of a physician, who has politely made me acquainted with the following particulars relative to his condition at that time:—Countenance pale, haggard, and sallow; pulse frequent and irritable; thirst; huskiness of the skin; occasional severe lancinating pain at the pit of the stomach, particularly after taking solid food; pyrosis; much flatulence; acidity at the stomach; rejection of all aliments, generally about half an hour after they had been swallowed; constipation, the evacuations being slender, pale, and scanty. Pressure over the region of the stomach detected a hard, firm substance, but owing to the extreme degree of suffering it produced, the limits of the hardened mass could not be clearly made out. Alkalies, mild laxatives, occasional doses of opium, with a regulated diet, seemed to produce a very beneficial effect; and, for a few days, the whole of the symptoms were so much relieved, that a reasonable hope of ultimate recovery was entertained. This apparent improvement lasted but a short time; every previous symptom returned with augmented severity, and opium combined with oxyde of bismuth was obliged to be frequently administered, to render his anguish tolerable.

At this stage of the disease I was sent for, about twelve months after he first consulted me, and continued in attendance till the patient's death. The following may be considered a brief outline of his symptoms on the 28th of May, 1829:—Severe local pain in the epigastric region, where a hard tumor could be distinctly felt, which was exceedingly painful on pressure; pulse frequent and irritable; constant thirst, with heat and dryness of the skin; frequent vomiting, which invariably quickly succeeded the swallowing of all aliments, the medicine previously mentioned excepted; an inability to take more than a small tea-cupful of liquid at any one time, the fluid regurgitating if he attempted to swallow a larger quantity; constipation; emaciation, œdema, and abdominal dropsy. I advised the following plan of treatment:—A seton to be made at the pit of the stomach; injections of strong beef-tea

to be frequently administered; the narcotic remedy to be continued, but food taken by the mouth to be as much as possible abstained from. From this plan, however, I did not expect much relief; and having made this statement to his friends, they did not choose to permit him to undergo additional suffering, unless I could promise more advantage than could have been consistently expected. Such were his sufferings, that he was obliged to take solid opium almost hourly; indeed, opium and brandy might now be said to constitute his entire sustenance. From this time, every important symptom previously enumerated became aggravated, till the day prior to his decease (Aug. 20, 1829,) when the sickness and pain left him.

Inspectio Cadaveris.—Body much emaciated; cavity of the abdomen contained several quarts of serum, in which large masses of lymph were floating; general appearance of the peritoneum rough, and somewhat tuberculated; gall-bladder distended with thick bile, its neck being greatly contracted from schirrous disease; the lower part of the œsophagus was singularly plaited and ridgy, or, in other words, raised into large, round, horizontal elevations; the stomach was externally hard and smooth, and preserved its circular form. On dividing it perpendicularly, I was astonished at the extreme smallness of an opening, three-fourths of an inch in diameter, surrounded on all sides by a firm brawny structure, nearly an inch and a half in thickness. On minute examination of the cut surfaces, it was found that the inner membrane was softer than usual, and slightly thickened; the peritoneal covering but little altered in appearance, the enormous deposit, constituting the chief part of the disease, being situated between them: its firm, brawny texture, intermixed with membranous bands, convinced me that it must be considered a fair specimen of schirrous disease. The cavity of the stomach was capable of containing only six ounces of fluid, its parietes being, as I have before mentioned, very much thicker than those of the left ventricle of the heart. The mucous membrane was very little diseased: in one or two points it had a puckered appearance, as though some time or other it had been in a state of ulceration. At the pylorus, several large nipple-like

prominences, covered by the lining membrane of the stomach, were discovered, producing a close resemblance to an enlarged and irregularly thickened os uteri. The niches left by the imperfect adaptation of the nipple-like enlargements at and near the pylorus, were scarcely large enough to permit the passage of thin fluids, when, the stomach and duodenum being removed, they were attempted to be urged through them. The arteries of the stomach were all enormously enlarged, although free from disease, and the neighbouring glands and cellular structure were increased in size and firmness. The intestines were in a very variable state of disease, being vascular, thickened, and even, in some part of their course, ulcerated. The other abdominal viscera were not conspicuously diseased. The head and chest were not examined.

CEREBRAL AFFECTION IN CHILDREN RESEMBLING HYDROCEPHALUS.

To the Editor of the London Medical Gazette.

SIR,

I HAVE been comparing Dr. Gooch's chapter on a complaint of children commonly attributed to congestion of the brain, in his late work "On the Diseases of Women," with Dr. Marshall Hall's pamphlet on "A Morbid Affection of Infancy, arising from Exhaustion, but resembling Hydrencephalus," which was analysed in your last number, or rather, copious extracts from which were given.

The conclusions to which Dr. Gooch's chapter on this interesting and important subject lead are, that a set of symptoms which, when they affect children, are always attributed to determination of blood to the head, sometimes arise without this state of circulation in the brain, from deficient nervous energy; and that in these cases the depletory treatment commonly employed is in the highest degree injurious, and that this condition requires nourishment and cordials. Now, although this truth was unknown to the practitioners of the profession, at least was not practically attended to, it had been already described by Dr. Abercrombie, in his

work on "Diseases of the Brain;" and last winter a paper had been read about it by Dr. Marshall Hall, at the Medico-Chirurgical Society: a short report of it was published in the Medical Gazette, before the publication of Dr. Gooch's work. Although he appears to have been alive to this form of disease long before he met with the above short notices of it, he very readily yields priority of announcement to Dr. Abercrombie and Dr. Hall. But Dr. Gooch's chapter leads to another conclusion equally interesting and important in a practical point of view to that already stated, and which had been noticed neither by Dr. Abercrombie nor Dr. Hall. He opened the heads of some children who had died of this complaint, and who had been kept for several days, by purging and bleeding, in a state of circulation "at the lowest ebb consistent with life," and then he found the blood vessels of the brain singularly empty, but an excess of serum in its ventricles; he concludes, therefore, that in the brain there may be effusion of serum from a state opposite to congestion, and that the depletory treatment which is used so actively to prevent it, may sometimes be the cause of it. This deserves to be looked closely into: if true, it is a curious and important circumstance. Yet neither Dr. Abercrombie nor Dr. Hall had noticed it—neither of them seem to have opened the children who died of these symptoms. It was not mentioned by Dr. Hall in his paper before the Medico-Chirurgical Society; and even in his more extended account of it, published since the appearance of Dr. Gooch's volume, he does not seem to be aware of it, as appears by the following extract:—"A state of exhaustion of the general system, as I have observed elsewhere, by no means precludes the possibility of *real congestion of the brain—it rather implies it. In extreme cases, there are not only the symptoms of cerebral congestion during life, but effusion of serum into the ventricles of the brain is found on examination after death.*" Is it not plain from this passage that if Dr. Hall were to find serous effusion on opening these cases, he would attribute it to cerebral congestion? Yet Dr. Gooch's cases render it highly probable that it may be caused by an empty state of the cerebral vessels. This conclusion, if true, is the most valuable part of Dr.

Gooch's chapter. His opinion appears to me to be highly probable, not only from the cases which he has related, which bear directly upon the question, but indirectly, from what takes place in other parts of the body.

So much has been said of late years of inflammatory dropsy, and depletory treatment is so constantly resorted to for it, that we seem to have forgotten the important facts that anasarca and copious effusion may take place into the cavity of the peritoneum in persons with broken-down health, and without any visceral disease; and may get well under the influence of country air, nourishing food, and tonic medicines. As this subject is at this time exciting considerable attention, I hope it will be directed toward this important pathological question, which at present seems likely to be totally overlooked.

I am, Sir,

Your constant reader,

* W. H.

September 26.

METHOD OF PREVENTING UTERINE HÆMORRHAGE OCCURRING AFTER DELIVERY.

*To the Editor of the London Medical
Gazette.*

SIR,

You will oblige your correspondent by allowing him, through the medium of your truly valuable Journal, to make known to the junior part of your readers the means he has lately found successful in preventing uterine hæmorrhage after delivery. The plan is simple, and is probably employed by those who have long practised midwifery; but your correspondent is not aware that it is generally taught, or that the superior advantages it appears to possess are duly appreciated by junior practitioners.

Perhaps no cases are so terrific to the young practitioner of midwifery as those of uterine hæmorrhage, because none are more fatal, or less under the control of medical skill. Of this truth the writer felt the almost overwhelming force, on being summoned to attend a patient who had had frightful floodings immediately after the delivery of each of her six children.

It suggested itself, that, as hæmorrhage from the partrurient uterus comes on generally immediately after the expulsion of the child, and this because the placenta is partly detached at this period, from the change of form which the uterus has undergone on parting with the fœtus, that if the uterus could be prevented from filling with blood until the birth of the placenta, all might go on well afterwards. This appeared probable, and the means employed to produce this state of things was thus effected.

The patient was found with the os uteri well dilated, and wanted only some expulsive pains to complete the birth. She was laid on her back, and an intelligent assistant was directed to place both hands on the distended uterus after each pain, to prevent the uterus rising again in the abdomen, by a gentle continued pressure. A few pains completed the delivery of the child: it was immediately transferred to the care of the nurse, and the accoucheur then took charge of the uterus himself. It appeared to want the contractile power; the hands were firmly applied till action came on; in two or three minutes the placenta was expelled, from being probably partially detached before. The uterus being now grasped, felt about the size of a cricket-ball. A small book was folded up in a long napkin, and this was fixed tightly around the body, in such a manner that the lower edge of the book prevented the upper edge of the uterus from rising above the pelvis. The patient was not left for some time, but no symptoms of hæmorrhage supervened. It remains for the reader to judge whether this mode of treatment prevented the patient from flooding, who had done so in every other accouchment, or whether it chanced that she was not under the circumstances on this single occasion to induce uterine hæmorrhage.

Another case, equally conclusive to the writer, has since occurred to him; but as the details of both are pretty much alike, the reader need not be troubled with them.

The novelty of this plan, if it be novel, is the making constant pressure on the uterus, so as to prevent its being distended with coagula previously to the expulsion of the placenta.

A YOUNG ACCOUCHEUR.

Birmingham, Sept. 20, 1829.

* We shall be much obliged.—E. G.

 tis Medicæ* tueri; potestas modo veniendi in pub-
 icum sit, dicendi periculum non recuso.”—CICERO.
 —

DISTURBANCE AT GUY'S HOSPITAL.

We alluded in our last Number to an attempt which had been made to create a disturbance at Mr. Key's Introductory Lecture; and we now recur to the subject, as affording one among many proofs of the good sense and good feeling which pervade the great majority of pupils, as well as of the contempt in which they hold those ill-disposed persons who endeavour to cajole them into a belief that, to violate the common courtesies of life, is to shew spirit and independence; and that to depress others is to elevate themselves.

The school at Guy's has long been *honoured* with the particular notice of a contemporary journalist; and, in his early volumes, he bestowed upon the establishment all the commendations it deserved—commendations, however, which were even then rendered remarkable, by the contrast they presented to his mode of treating other institutions of equal merit. But having been recently turned out of St. Thomas's, and burning with indignation, he transferred his patronage to Guy's; and our readers may possibly remember the terms of unqualified approbation in which this establishment was spoken of. But, unluckily, the medical officers of Guy's Hospital happened to be *gentlemen*, and soon manifested symptoms of uneasiness at being thus singled out for commendation in a quarter so suspicious; till, at length, one of them having expressed his opinion of our contemporary in terms by no means flattering, the whole sys-

tem was instantly changed. The affront offered by the medical officers of St. Thomas's had been great, but it was private; in this instance the offence was public: so much blacker was the injury, and so much deeper must be the revenge. Mr. Travers, who had been persecuted with all the malignity of relentless hatred—Mr. Green, who had been insulted even to the extent of fictitiously representing him as in the list of his contributors—Mr. Tyrrell, whose prosecution and whose triumph had been the theme of the bitterest and most slanderous comment—all were forgotten, in the overwhelming and absorbing purpose of ruining the school at Guy's. The distinguished individual whose name had given lustre to British surgery, was now selected as the butt of his ribaldry, and week after week were the pages of his journal devoted to insulting the man, but for whose too easy acquiescence in suffering his lectures to be reported, the publication would never have risen into notice. Of the conspiracy by which it was attempted to carry his vengeance into effect, through another of the same name, it is unnecessary for us to speak; it has proved a signal instance of retributive justice, and, by exposing the machinery which kept the system of slander in operation, has contributed more than any other circumstance to its ruin. One would have expected that repeated failures, if they could not generate better principles, would at least have inspired caution. Experience, it is said, teaches fools; but where folly is blinded by passion, the lessons of the past are forgotten in the pursuit of revenge.

It appears that, last winter, one of the teachers at Guy's—Mr. Key—mentioned to his class that it was intended to give a prize to the most deserving surgical pupil. This announcement was made, not in the prospectus of the lectures—not in the introductory address—not at

a time or under circumstances which could have rendered it an inducement for pupils to enter—but after one of his lectures at an early period of the season. Such prize, however, was not given. We state it thus broadly, because we wish to give the circumstances precisely as they stand. We “nothing extenuate;” would we could say of *others*, that they “set down nought in malice.” The fact of Mr. Key having mentioned the design of establishing a surgical prize at Guy's, was a sufficient indication of his wishes upon the subject; and had he stood alone, would have been the guarantee of its fulfilment. But why, it will naturally be asked, did not Mr. Key offer some explanation to his class, when he found that circumstances had occurred to prevent him from carrying his intentions into effect? We do not speak “on authority,” but we apprehend that this omission arose from two causes—first, that no explanation was demanded; and Mr. Key, finding himself in a situation of some embarrassment, was not anxious to volunteer it; but, secondly, this backwardness to explain depended upon the impossibility of doing so without involving another person, whose conduct he did not wish to place in disadvantageous contrast with his own.—This is the state of the question, so far as we can gather from what fell from Mr. Key, when he addressed his class, on Tuesday evening. For our own parts, we are free to confess that, in our opinion, Mr. Key carried his delicacy in this respect too far, and that it would have been better, having once expressed his desire to institute a prize, to have explained the existence of unexpected difficulties at the time they occurred.

Instead, however, of giving to this gentleman the credit to which his anxious wish to promote the interests of the

pupils entitled him, every effort was made to represent him as guilty of having held forth, as an inducement for pupils to enter to his lectures, advantages which were not realized, and as having deliberately and wilfully practised an imposition. Well knowing that till the re-assembling of his class no proper opportunity of explanation could now present itself, and aware that Mr. Key was not to be driven from his purpose by intimidation, the opportunity of representing this delay as a refusal was too good to be lost, and no pains were spared to impress the pupils with the idea, that Mr. Key had first broken his promise, and now, by refusing to explain, was adding insult to injury. The notes of defamation were sounded on the usual instrument of slander—the secret whisperings of practised backbiters were passed from ear to ear—placards were pasted on the walls, and handbills circulated through the lecture-rooms, in which the pupils were “solicited” to insult their teacher. In short, all the machinery by which a few profligate individuals earn a disgraceful subsistence, was put in operation, and every effort made to get up a new “tragedy” at Guy's. We subjoin an accurate report of the proceedings.

It was fully understood that an attempt was to be made *publicly* to insult Mr. Key, on his entrance into the theatre, and the following *characteristic* note, *printed* and extensively circulated, left no doubt as to the source whence this disgraceful hostility had emanated:—

“The Pupils of Guy's Hospital are particularly solicited to join in expressing their indignation of Mr. Key's ungentlemanly conduct.”

At eight o'clock Mr. Key entered the lecture-room, and we never recollect to have seen Sir Astley Cooper more cordially received. The long-continued applauses bestowed on the lecturer were the best and most convincing proofs of the little effect pro-

duced by the machinations to which we have just alluded. On their conclusion, two or three hisses were heard; and to one individual, who had particularly distinguished himself by the coarse and disgusting vulgarity of his expressions, the attention of the class was directed by Mr. Bransby Cooper, who was sitting very near him, and who, addressing Mr. Key, requested him not to proceed until this individual either quitted the theatre or ceased to interrupt the lecture. This declaration was immediately succeeded by universal cries of "Turn him out!" "Turn him out!" which was, however, prevented by Mr. Key commencing his address, of which the following is a correct outline:—

"Gentlemen,—I feel most truly grateful to you for the reception you have given me this evening—a reception the more gratifying as it shews me that your feelings perfectly accord with my own as to the source and nature of the machinations which have set this paltry paper in circulation (continued applause). I am one of the last to complain of any attacks, however unmerited they may be, made upon my public character; I have been too long used to public life to notice any slanders, however atrocious; and I am prepared to receive a thousand times as many shafts without bestowing upon them more notice than I have hitherto paid to them. But, when an attack assumes this garb; (holding up the paper) when the standard of hostility is attempted to be raised between the lecturer and his pupils; when pupils 'are particularly solicited' to visit with their indignation the 'ungentlemanly conduct' of their teacher, it is high time that the lecturer should cease to be silent. What, gentlemen, is the nature of the accusation on account of which you are 'particularly solicited' to shew your indignation? From all I have been able to learn of this grave accusation, I believe that it relates solely to the non-distribution of the prize at the conclusion of last season; and upon this point I think it right to say a very few words. In the first place, the distribution of a prize was an act perfectly gratuitous on my part; secondly, the circumstance of a prize being given was not advertised in the hospital papers—it was not mentioned at the commencement of the course of lectures—it was not until the end of the fourth lecture,

when the pupils had fully entered, that any announcement of a prize was made. But still I am free to confess that a promise of a prize was distinctly made, and I am also willing to admit that this promise was not fulfilled. The circumstances which gave rise to this omission I am unwilling to advert to farther, as the explanation would necessarily involve another individual; and I am perfectly content to bear the whole brunt—the whole odium of this charge; at the same time you will do me the justice to believe that the omission was one not dependent on me, and that none could regret it more than myself (applause).

"Now, Gentlemen, I beg you distinctly to understand that not one word of this explanation would I have uttered had I entertained the least suspicion that this miserable production had emanated from one of you. But I do not believe that there is a pupil attending this school who could be guilty of an act so unkind, so ungenerous as regards myself, so deliberately base and cowardly as regards its author."

[Here the plaudits continued for several minutes, during which time the conduct of the individual above alluded to became so outrageous that Mr. Cooper seized him by the collar, and insisted upon his quitting the theatre. Several of the gentlemen immediately rose to assist in putting Mr. Cooper's threat into execution; and he would have been quickly expelled had not the lecturer intreated them to desist. Mr. Cooper then allowed him to resume his seat, on condition that he should remain quiet during the rest of the evening. After some time, order having been restored, Mr. Key proceeded:—]

"I know, Gentlemen, too well the impure source from which this paper has emanated, but my lips shall not be defiled by giving utterance to the name. I know, too, the agents who have been employed to circulate these papers, but their utter worthlessness, and their obscurity, shall be their protection. Gentlemen, this evening was intended to witness my degradation. I ask you, am I degraded in your esteem (loud and continued applause)?" Am I degraded in the estimation of my colleagues?—their presence testifies the contrary. Am I degraded in my own esteem?—No. If ever I had reason to be proud, the result of this evening makes me truly so. I am

proud that, of all the lecturers and teachers of this school, I alone am found to be vulnerable. I am proud that, after the most industrious attempts to find a blot in my character, this, like the heel of Achilles, should have been my only vulnerable point (continued applause).

"Gentlemen, we have pretty good evidence that one of the agents concerned in this miserable plot is at present amongst us: now, then, is the time for my revenge. To him will I address myself; and if there be another present who, from a fellow feeling, has leagued himself with this malignant plotter; if there be another here who has been weak or wicked enough to become the agent of this worker of evil, let him return home with his comrade, and report to his employer the success of his mission; let him describe to him the utter failure of all his plans; let him say that he found a large and respectable class, who, in spite of his 'particular solicitations' to the contrary, received their lecturer with demonstrations of affection and applause. Let him say that he saw that lecturer stand firm in the consciousness of his own innocence; let him say that he saw him surrounded by his colleagues*, men of high honor, who came to support him by their presence; let him tell his employer that the scene of degradation which the author of this paper had anticipated, was converted through the means of that very instrument into a scene of triumph; and, to fill his cup of bitterness to the brim, let him describe what the result of this conspiracy has been, where the accused is a man of integrity, and where the assembly of his judges possess feelings of honour and manly independence."

The feelings of one or two individuals, who were known to be concerned in this transaction, may be better imagined than described; they made several attempts to address the class, but the moment they rose, their voices were drowned by acclamations from all parts of the theatre.

We congratulate the profession, and especially the school of Guy's Hospital, on the total failure of this disgraceful

attempt to interrupt a public teacher in the discharge of his duties, and to convert the lecture-room into an arena of angry contention between him and his pupils. We trust that the time is not far distant when every member of the profession will follow the example of the students at Guy's, and shew their full conviction that no portion of their interests or honour can, with safety, be trusted to those with whom honour is a word unknown, and whose sole object is to sell the greatest possible number of their weekly calumnies.

Under the mask of confirming the independence, and advancing the best interests of the profession, the agents of this system have dishonestly but sedulously laboured to introduce universal suspicion and distrust. The medical world was amazed, and, for a time, almost paralysed, by the impetuosity and the apparent boldness of the attacks. Some thought, that as plagues and tempests are said not to be entirely without their use in the natural world, some such uncertain and negative good might possibly be associated with this moral tornado. It was soon evident, however, that this hope was vain, because the interests of those concerned in the publication were not in accordance with the interests of the profession.

The practical evils arising from the *Lancet*, like the devastations of the tempest, will require some time for their entire removal; but its party is now reduced to a few obscure individuals—its influence is gone; and we believe, ere long, it will be regarded as the reproach of the profession that it ever had existed. Perhaps it ought to be admitted, in favour of the unprincipled and unfortunate persons connected with it, that their conduct has, to a certain extent at least, been the result of necessity, from feeling conscious that they belong to a class of society who are indebted for their notoriety, and almost

*Right, Dr. Addison, Mr. Cooper, and others, were present.

for their existence, to the maintenance of suspicion, discord, and confusion.

The Editor of the *Lancet*, commenting on this disgraceful transaction with all the bitterness of a disappointed partizan, asks—"Who is Charles Key?" The question is easily answered: Mr. Key is a gentleman of unimpeached character, and an accomplished surgeon, engaged in the actual practice of his profession. But this question, so insolently put, naturally suggests another:—Who is he that asks? Who is Thomas Wakley? What is his character, private or public? "What light has he ever made in the darkness—we mean the darkness of professional error, to which he can now revert with triumph, and remember without shame that he kindled it?"

PUBLICATION OF MR. LAWRENCE'S LECTURES.

It is industriously insinuated in the *Lancet*, that some advantages are afforded by Mr. Lawrence to that journal in the publication of his Lectures; in other words, that Mr. L. corrects the press. This we positively deny, and dare the Editor of the *Lancet* to assert that it is so.

Much as we have differed with Mr. Lawrence on some points of professional politics, we have always treated him as a man of science and a gentleman, and, therefore, had no hesitation in asking his consent to publish his lectures. With us, his permission to do so—full, absolute, and unconditional—was a *sine qua non*, before we ventured to announce our intention, and such permission he communicated to us *both verbally and in writing*. After all the vapouring in the *Lancet* about *our* disrespect towards Mr. Lawrence, it will scarcely be credited, but is, nevertheless, literally true, that Wakley had the impudence to ad-

vertise the publication of that gentleman's lectures in his journal, before he thought proper even to acquaint him with his intentions,—clearly shewing that he meant to appropriate them to himself, at all hazards, as he had been accustomed to do the intellectual property of others; and yet he talks to us of disrespect! *Quis tulerit Gracchos de seditione querentes?*

CURIOUS PLAGIARISM.

In the September Number of the *Medico-Chirurgical Review*, the respectable and intelligent Editor accuses Dr. Gooch of having borrowed his opinions on insanity from Dr. Burrows; in proof of which he gives a sentence from these two authors, in which the same thought is expressed in almost the self-same words. In 1829, Dr. Gooch writes thus: "It appears, therefore, that emotions of mind are capable of disturbing the organs of the body; and though moral causes in themselves, they may be physical in their operation." (*Diseases of Women*, p. 187.)—But, in 1828, Dr. Burrows had written thus: "All emotions of the mind, it is evident, are capable of disturbing the corporeal functions; and though in themselves moral causes, they become physical in their operation." (*On Insanity*, p. 22.) Now the sentences are so strikingly alike, that we think it quite clear that the one was copied from the other, and as Dr. Gooch's volume was not published till a year after that of Dr. Burrows, it *seems* logically to follow that the former copied from the latter. Now it is quite true that Dr. Gooch stole this sentence—not, however, from Dr. Burrows, but from an author whose work was published nine years before Dr. Burrows's, and from whom Dr. Gooch has a right to steal as much as he likes—*himself*. If our contemporary will take the trouble to open the *Transactions of the College of Physicians* for 1819, and turn to Dr. Gooch's paper on Puerperal Insanity, he will find, in his summing up at the end, the very sentence which he accuses him of copying from Dr. Burrows. *It is, therefore, quite clear that Dr. Burrows copied the sentence from Dr. Gooch*. He certainly read Dr. Gooch's paper, for he not only

quotes it repeatedly, but he has copied two errors of quotation from it, which we leave the critic and the reader to find out. We can easily explain the plagiarism, however, without any uncharitable supposition. In reading Dr. Gooch's paper, Dr. Burrows, having perhaps a tenacious memory, retained not only the thought but the phrase; and when, years afterwards, he came to write on the same subject, found the sentence in his mind, and fancied that it had grown there. This habit of unconscious plagiarism is said to have been remarkable in Lord Byron; to be equally remarkable in another distinguished author, still alive; and we have observed it in other men, to an extraordinary extent, of whose literary honesty we have not the smallest suspicion. As to Dr. Gooch's borrowing his ideas from Dr. Burrows, the germs of them all may be found in his paper of 1819, and in their present mature state, on all the leading points of the subject, such as the condition of the mind, the state of the cerebral circulation, the influence of blood-letting, the treatment of the disease, and, in some cases, the propriety of seclusion. Their opinions, so far from being borrowed, are wide apart from one another.

Every body remembers Mr. Canning's story of the jealous dramatist, who accused a rival dramatist of stealing from him his thunder; and if these things are indulged in, we shall have one author accusing another of stealing his *ands* and his *ifs*, his colons and his periods.

PROCEEDINGS OF SOCIETIES.

MEDICO-CHIRURGICAL SOCIETY.

THE meetings of this Society commenced on Tuesday evening, on which occasion, in the absence of Dr. Roget, the chair was filled by Mr. Lawrence.

The first part was read of an interesting paper on uterine phlebitis, by Dr. R. Lee; but as the subject was not completed, we shall postpone our account of it till after the next meeting.

GUY'S PHYSICAL SOCIETY.

IN deference to the antiquity of this Society, we deem worthy of record a

revolution it has recently experienced, by which it is founded on an entirely new basis. A society established so far back as 1772, earlier by a year than any other in the metropolis—the parent, therefore, of the rest—cradled during the infancy of modern medicine, and, for above half a century, ministering to its rapid advance—such a society we cannot look on but with interest; especially when, after seeming decay, it is again rising into the freshness and vigour of a second youth.

The old society was declining, deserted by many of its members, and embarrassed by debt. The remaining members, therefore, thought it prudent to resign the library, their only property, into the hands of the treasurer (their creditor), on the condition that he should re-model the society, allowing them the enjoyment of their former privileges. This has been done; and with an improved library, and a more simple and liberal code of laws, the society is now re-opened. With a view of promoting a useful object, we notice the first meeting, though it is not our intention hereafter to report the proceedings.

The first meeting of the new Society was held on the 3d inst. Dr. Bright in the chair.

The PRESIDENT opened the business of the evening by reading a sketch of the future regulations of the Society, furnished by Dr. Hodgkin. These are not yet reduced to proper form, but in substance are as follows:—

1. Members of the old Society shall retain all their former privileges, as to use of the library, presence at meetings, &c.

2. The library shall be open to all pupils of Guy's Hospital, at hours hereafter to be appointed.

3. Meetings of the Society shall be held once a fortnight (Saturday, 8 P.M.) for the discussion of medical papers and cases of disease, to which all pupils of the Hospital, and visitors (by ticket) may be admitted.

4. Members of the Society, pupils, and the profession generally, are invited to furnish cases and papers for discussion.

5. None are *required* to furnish papers, &c. or are liable to fines or penalties in any form.

6. The direction of the Society being in the hands of the Hospital Council,

no private business, or act of legislation, can be introduced into its meetings.

7. The members, medical officers, teachers connected with the Hospital, and visitors, shall meet in the library for conversation, half an hour before each public meeting; when tea will be provided.

Having read this statement, the President made some forcible remarks on the advantages of societies in promoting medical discussion, especially by inducing junior members of the profession to write dissertations on particular subjects. Such dissertations, he thought, were always beneficial to the authors, and in very many cases proved important to the profession and the public; an instance of which he adduced in the case of the late Dr. Currie, whose views of fever, and its treatment by cold affusion, had their origin in a paper which he wrote for the Royal Medical Society of Edinburgh.

After some discussion on the mode of conducting the business of the Society, Mr. ILIFF stated that he would, at next meeting (October 17th), bring forward a case of small-pox after vaccination, with some remarkable circumstances.

HOSPITAL REPORTS.

EDINBURGH ROYAL INFIRMARY.

Removal of the Superior Maxillary Bone.

ELLEN GRANT, æt. 54, admitted under the care of Mr. Lizars, July 30th. Three weeks previous to admission, had laboured under general dropsy. States, that three weeks ago she felt pain in the situation of left superior maxillary bone; and that, for a month previously, on blowing her nose, a bloody fluid escaped from the nostril. Five days ago, Mr. Lizars extracted a mucous polypus from her nose, but the pain in the region of the superior maxillary bone continued lancinating and very severe during the night, preventing her from sleeping.

There is considerable swelling of the cheek, and the tumor is exceedingly painful on pressure. It projects into the posterior part of the left nostril, and towards the cheek bone; but the orbit is not at all affected. Pulse 100, and of moderate strength; appetite impaired; countenance pale; thirst; bowels constipated.

Ordered a purgative draught.

August 1st.—To-day Mr. Lizars removed the diseased parts. The patient was laid on

her right side, and the trunk of the temporal and internal maxillary arteries was secured immediately below the digastric muscle. A ligature was also placed on the external jugular vein, which had been divided by the first incision. An incision was now made with a bistoury, from the angle of the mouth to the masseter muscle. The left lateral cartilage of the nose was slit open close to the septum, and the knife carried downwards, through the upper lip, near the labial fossa. The flap thus formed was then dissected up towards the orbit and malar bone, so as to expose completely the diseased mass. The mucous membrane lining the floor of the left nostril, the gum, palate, and velum pendulum, to the left of the longitudinal palatine suture, were divided; and the separation of the bone was accomplished by the saw, Mr. Liston's forceps, and a pair of strong scissors; but the orbitary plate of the superior maxillary bone was carefully separated from the eyeball by the handle of the knife. The tumor was of a medullo sarcomatous structure, and adhered to the pterygoid processes of the sphenoid bone, a diseased portion of which necessarily remained attached. A portion of the malar bone contiguous to the tumor, and involved in the disease, was removed. Several mucous polypi adhered to the left inferior turbinated bone. The facial artery was secured, and some lint placed in the wound, in consequence of a slight oozing at its upper and posterior part. The edges of the wound were approximated with sutures and hare-lip pins, and one or two light compresses were applied and retained by a bandage.

Immediately after the operation, 50 drops of laudanum and 3j. of tincture of hyoscyamus were administered. No secondary hæmorrhage. Slept well.

August 2d.—Face somewhat swollen; has little or no pain, but complains of slight sore throat. Pulse 92; bowels open.

Habeat haustum purgantem et haust.
Anodyn.

August 4th.—The pins have been removed. All the wounds are healed except a small portion near the ear; this, however, is united internally. Ordered light nourishing food.

5th.—One dark scanty stool has been procured by an enema. The lint, which was inserted within the mouth, has been discharged. The mouth to be washed occasionally with warm water.

8th.—Mouth to be washed with a lotion containing myrrh and cinchona.

Habeat Vini Albi 3vi.

9th.—Habeat Vini Albi 3viii.

10th.—Mouth to be washed with a weak solution of the chlorate of lime.

16th.—The external wounds being healed

and the patient doing well, she requested to be dismissed*.

Dislocation of Femur upwards and forwards.

David Craig, æt. 38, admitted under the care of Mr. Lizars, Aug. 29.

About an hour previous to admission he had fallen about 60 feet from the mast head of a ship, and sustained dislocation upwards and forwards of the left femur, and fracture of several ribs of the same side, and of the right olecranon. The head of the femur was lodged over the pubic attachment of the pectineus muscle, its apex was distinctly felt in the groin, and the pulsation of the femoral artery could not be perceived. The whole limb was turgid, and of a blue colour. The thigh admitted of considerable flexion, and the limb was shortened, and so much everted, that the foot was placed at a right angle to its fellow. The dislocation was easily reduced by gradual extension and sudden rotation of the limb inwards. The right arm was extended and retained in that position by a splint placed on its fore part.

Evening.—His pulse being full and quick, and as he complained of pain in the left side, ʒxx. of blood were taken from the arm.

Rx Sulph. Magnesiae ʒiiss.

Vini Antimonii. ʒij.

Aquæ ʒviii. ʒij. every two hours.

30th.—Pain diminished; pulse 80; bowels open.

Sept. 15th.—No untoward symptoms supervened, and the patient recovered rapidly.

Disease of Kidney, producing symptoms of Stone in the Bladder.

John Douglas, a seaman, æt. 47, admitted under the care of Mr. Liston, August 15.

Three years ago he sustained an injury of his side, in consequence of a fall; and soon after the accident experienced some difficulty in making water. Twelve months afterwards he passed a good deal of blood in his urine. He has constant micturition, especially during the night; and complains of severe pain after the bladder is emptied. His urine often stops suddenly while flowing in a full stream, and while making water he feels pain at the extremity of the penis. The urine is coagulable by heat. On sounding him no stone can be discovered.

Rx Opii gr. iij. Fiat suppositorium.

Habeat Emulsionis Camphoratae ʒss. quater in dies.

17th.—Has become incoherent, is very weak, and evidently sinking.

23d.—Died at one p.m.

* Three days afterwards she suddenly expired, and no dissection could be obtained.

On dissection, no calculus was found; bladder sound; surface of right kidney nodulated; scarcely any of its natural structure remained, it being occupied by numerous abscesses of various sizes, which contained thick purulent matter of a cream colour. The abscesses appeared to have been of considerable duration, their parietes being dense, and lined with firm lymph deposited irregularly, and in some places in considerable quantity. They communicated with the pelvis of the kidney, which was much contracted, slightly thickened, and also lined with lymph. The left kidney was enlarged to three or four times its ordinary size; its tunica propria was considerably thickened, and in many places elevated by small superficial cysts, containing pus. The whole substance of the organ was of a deep red colour; the cortical part was enlarged, and contained deposits of lymph, and numerous minute abscesses. The uriferous part was similarly, but more extensively diseased; the situation of the papillæ was occupied by irregular masses of lymph; and the pelvis and infundibula much enlarged, and otherwise in the same condition as those of the right, contained much purulent matter.

ST. THOMAS'S HOSPITAL.

Wound of the Arm followed by Aneurism—Effects of Pressure.

THOMAS COLLETT was admitted into William's ward on Sunday, p. m. May 3d, having in a quarrel been stabbed through the left arm with a knife, which passed in an oblique direction between the radius and ulna: the wound on the anterior part of the arm was situated at the commencement of the upper third, over the radial artery.

The people who brought him to the hospital said there had been a good deal of hæmorrhage, and described the blood to have escaped by jets. A surgeon had been called in, who had closed the wound with sutures and compresses.

When admitted he was very faint; the arm was much swollen, and the arteries at the wrist imperceptible: there was likewise great numbness. Ordered to bed; the arm to be supported on a pillow; spirit wash to be kept constantly applied, and when reaction had taken place, a dose of senna and salts.

Half-past 8, p.m.—Swelling of the arm much diminished; arteries at the wrist pulsating rather strongly; bowels had been relieved by the house medicine.

5th.—There is a small pulsating tumor at the wound, on the anterior part of the arm, appearing to communicate with the radial artery, which can be traced both above

and below the tumor. The general swelling much diminished.

Cont. remedia. Mist. Sennæ Comp.
p. r. r.

11th.—The tumor has been gradually increasing in size; is painful on pressure: the pulsation is perceptible to the eye; there is also pulsation at the posterior part of arm, round the situation of the wound there.

13th.—Mr. Tyrrell ordered V. S. ad \mathfrak{z} xij. (the pulse being rather sharp and quick), and a roller to be applied from the fingers to the elbow, a compress of lint to be previously placed over the tumor, and confined with Emp. Rubr.

15th.—Tumor much the same; no increase in size. As pressure above completely stopped the pulsation, a small tourniquet* was applied to the upper arm, in order to diminish the circulation in the brachial artery, and so contrived as not to prevent circulation in the collateral vessels. The roller to be continued on the limb, and V. S. ad \mathfrak{z} vij. Cold applications.

18th.—Pulsation still continues. Tourniquet tightened, so as completely to stop the pulsation.

19th.—Tourniquet was loosened by the patient this morning, in consequence of the pain it occasioned and the tumefaction of the arm. The pulsation in the tumor is certainly diminished.—Contnr.

25th.—Has been no pulsation since five o'clock this morning.

26th.—No pulsation.

27th.—Slight return of pulsation.

29th.—Bandages, &c. removed for the first time; tumor gone; wound not quite healed. There is a circumscribed pulsation, which appears to communicate with the radial artery. The pulsation on the posterior part of arm gone.

Cont. omnia.

1st June.—Pulsation continues, in consequence of the tourniquet having slipped.

5th.—Some pulsation; anterior wound healed; no tumor. In consequence of the tourniquet not affording sufficient pressure on the brachial, and its liability to slip, a common one was applied, contrived so as only to press on the artery.

6th.—No pulsation since yesterday; but in consequence of the swelling of the arm and hand, which is quite cold and benumbed, the tourniquet is to be slightly relaxed.

8th.—No pulsation since the application of the larger tourniquet.—Cont.

* A broad flat piece of board was placed under the tape of the tourniquet on the outer part of the arm, to carry the tape clear of the anterior and posterior surface of the limb, so as not to interrupt entirely the circulation.

13th.—Pulsation very slight.

16th.—No pulsation. Cont. Tourniquet still further relaxed.

July.—Continued improving, and, instead of bandages and tourniquet, Emp. Rubr. was applied from the fingers to the elbow. This was continued till the 30th July, when he left the hospital, with perfect use of the arm, and but a very slight circumscribed pulsation remaining.

ST. BARTHOLOMEW'S HOSPITAL.

Fatal Disease of the Thyroid Gland.

JANE GRIFFITHS, æt. 40, from the county of Lincolnshire, was admitted under Mr. Earle, August 28th, with a tumor of extraordinary size, occupying the whole front and sides of the neck, and pressing on the trachea so as to threaten immediate suffocation.

From what few words she could be heard to articulate, it was ascertained that she had first perceived the swelling only one year since; but that lately it had increased very rapidly, and become a great source of inconvenience to her. There is an indistinct feeling of fluctuation in some parts of the tumor, the whole of which is soft to the touch. Large veins traverse the tumor in different directions.

The poor woman seemed to be in *articulo mortis*, suffering greatly from difficulty of breathing; and nothing was likely to afford any chance of relief. She was supported by pillows in bed, and the breathing thus rendered somewhat easier. Thirty leeches were applied to the tumor, but before the bleeding from these had ceased the patient died.

Dissection.—The integuments were dissected off the tumor, and an incision made into its anterior part, when it was found that the disease was of a medullary nature, involving the whole of the thyroid gland; a thick cream-like fluid, with soft whitish matter, pervaded the whole structure. The disease did not present the usual firmness of substance of common medullary productions; but had a more semi-fluid consistence. The lungs were also diseased throughout, and in them were found small tubercles or cysts, thickly studded, containing a similar matter.

[The following are some of the Cases alluded to at page 81.]

CASE I.—Burn, treated with Nitrate of Silver.

James Harris, æt. 27, by trade a baker, was admitted into Powell's ward, on the evening of the 15th May, with a burn, about the size of a crown piece, on each foot,

which had existed since the early part of the morning. The whole of the right foot, and about the lower fourth of the same leg, were in a state of acute inflammation, which was apparently increasing very rapidly. In the left foot, the inflammation was confined to the neighbourhood of the sore. The *Argentum Nitratum* was immediately applied over the sore and the whole of the inflamed surface of the right leg, its application being extended a little beyond the margin of the inflammation in every direction. An adherent eschar was also formed over the sore on the left foot, and the little inflammation which existed around the sore was subdued by the same application.

16th.—There is no extension of inflammation, and the eschar over each sore is perfectly adherent. The skin, from a state of great tension, has become wrinkled, and much vesicated. After puncturing the vesicles with a finely-pointed lancet, the remedy was again slightly applied over them: this was repeated the following morning, and, with the exception of a dose of *Cal.* and *Jalap.*, nothing further was administered to the patient. He was, however, not discharged from the hospital till the 23d, on account of a rather doubtful eruption which appeared on his body.

CASE II.—Bite of a Cat, treated with Nitrate of Silver.

Francis Uncle, a very stout man, æt. 38, applied at the hospital on Wednesday, the 13th May, about two o'clock, P.M.; states that on the Monday evening previous he was bitten on his thumb in two places by a cat, but felt no uneasiness until this morning, at which period he awoke in excruciating pain. His thumb, fore-finger, and the whole of the dorsum of the hand, as high up as the wrist, are now greatly inflamed, much swollen, and exceedingly painful. The *Argentum Nitratum* was immediately applied over the whole inflamed surface, and its application extended, as in the preceding case, a little beyond the margin.

Ordered *Infus. Sennæ Comp.* ʒij. statim.

14th.—The inflammation has slightly extended in one direction, over which the *Argentum Nitrat.* was again applied. The skin has become much wrinkled and slightly vesicated. There is no pain or uneasiness, and the swelling is evidently much diminished. The vesicles were now punctured, and the remedy again slightly applied: this was repeated the following morning, when the patient requested to be permitted to resume his occupation, which he was able to do on the Monday following.

CASE III.

Wound received in Dissection, treated with Nitrate of Silver.

A medical student having slightly scratched his thumb with a saw, on Friday, August 28, whilst opening a head, felt no inconvenience until the Sunday evening following, when there was slight increase of heat and smarting pain in the part. During the night the pain, heat, and swelling, increased considerably, but by the constant application of cold water, they were so far abated as to prevent any thing further being done in the morning.

1st Sept.—Inflammation in the thumb is again considerably increased, and has extended some distance up the absorbents of the arm, and there is slight tenderness in the axilla. A number of leeches were applied, and after them a bread and water poultice. A large dose of calomel and antimony was taken. Nothing further, with the exception of continuing the poultices, was done until the 5th, when the absorbents became reddened with increase of heat and slight tenderness along their course. There was also increased pain in the axilla, but the thumb was free from pain and heat.

The *Argent. Nitrat.* was now applied along the course of the absorbents, from the wrist nearly to the axilla.

6th.—There is not the slightest tenderness along the course of the absorbents, and the pain in the axilla is greatly diminished. The skin is very much vesicated, and the same treatment as that mentioned in the two preceding cases, was had recourse to.

9th.—The thumb, from a rather too free use of it, has again become much enlarged, hot, throbbing, and very painful. The *Arg. Nitrat.* was now applied in the same manner over the thumb—in less than eight hours it was evidently diminished in size, and in a few days, without any further application or recurrence of unfavourable symptoms, was quite well.

[Though this cannot be called an *Hospital* case, we have taken the liberty of placing it along with the others.]

NOTE FROM MR. COSTELLO.

To the Editor of the London Medical Gazette.

SIR,

In a letter to your Gazette, dated Oct. 6th, Mr. Anthony White is pleased to declare, "that, in any correspondence he may have had with any person in Paris, my name was never mentioned, and that no case was found by him for me or any one else."

I do not quarrel with Mr. White's asser-

this, he continues to use and to exert it; the disturbance increases, the part begins to swell,—he soon finds that he is unable to move it without great pain, and he seeks medical assistance. When you see a case such as this, you will find the inflammatory affection already pretty fully developed, and you will observe that it is characterised by four circumstances: you see that the part is preternaturally *red*, and that it is *swelled*, *hot*, and *painful*. The swelling affects the entire hand, but does not present the same character over the whole of the part. In the immediate situation of the wound, supposing it to be on the finger, or the palm of the hand, you will perceive that the swelling is tense and firm. If the affection has extended from the hand to the forearm, the tumefaction will be of a firm character, particularly about the wrist; but if you examine the back of the hand and forearm generally, you probably find that the swelling is soft, and what we term *oedematous*; you observe also that the swelling is more extended than the redness.

The redness is of a bright scarlet or light crimson tint; that is the kind of colour which we may suppose would be produced in healthy persons by an increased quantity of arterial blood in the part;—it does not exhibit the hue that is produced by venous blood. The redness is most intense in the immediate neighbourhood of the injury, and from this it is gradually shaded off into the part which is sound.

The heat is sensible to the touch, so that, when we put the hand upon the part, we can perceive that the inflamed portion is considerably warmer than the rest. This difference then is obvious to the sense of others, and the patient himself feels a very intense burning heat in the part; but if we come to examine its temperature by the thermometer, we do not find that the actual heat has increased so much as the sensation of the patient might lead us to expect; in fact we do not find that it is beyond the natural temperature of the blood. The temperature of the blood is ascertained to be from 90 to 100 of Fahrenheit's thermometer; and however intense the feeling of heat experienced by the patient, we find that the actual temperature of the affected part does not ascend beyond this in any case of inflammation. This is a point that has been particularly investigated by Mr. Hunter. He excited inflammation in the cavity of the chest, and in the vagina and rectum of an ass; and he found that the temperature of those parts never rose, under any inflammation that he could produce, beyond that of the natural temperature of the blood. If we place a blister on the chest, and then examine the temperature of the part from which the cuticle has been removed, we find that the thermometer will rise about two degrees higher

than when applied to the surrounding uninfamed skin; and if we perform the same experiment on the extremities, we find it ascend four, five, or six degrees, as compared to the adjacent skin, because the temperature of the extremities is naturally lower than that of the parts nearer the centre of circulation. In one instance Mr. Hunter was operating in a case of hydrocele: he introduced a thermometer at the puncture in the scrotum, and found the temperature of the parts to be 92° of Fahrenheit. On the following day, when inflammation had supervened, the temperature had risen to 98½°. This was a considerable increase, amounting to 6½°, yet even here the temperature did not go beyond the natural heat of the blood.

The pain of the inflamed part is, in the first instance, slight, but gradually increases. It is augmented on pressure, and aggravated by any attempt at using the limb. In the first instance the patient experiences something of a dull aching pain, but as the inflammation proceeds it assumes a peculiar character, attended with throbbing, and a sense of pulsation in the part. The patient seems, as it were, to perceive the increased action of the blood-vessels; and this is not merely a circumstance suggested by the sensation of the individual, for if we place the fingers on the arteries leading to the inflamed part, we find that there is a considerable augmentation in the actual force of the pulsations. In inflammation of the hand, which we are now considering, we perceive that the pulse at the wrist of the affected limb is much fuller, stronger, and harder, than on the opposite side. In fact, we often find, if the inflammation be very considerable, that there is a very marked difference in the pulse of the two sides. Under these circumstances this throbbing, or preternatural pulsation, extends perhaps along the arteries as far as the elbow, and may be felt, through the muscles that cover the vessels, in the fleshy part of the arm. In conjunction with this increased action in the principal arterial trunk that leads to the inflamed part, you find a corresponding distention in the veins which convey the blood away from it. When the hand is thus inflamed, if you uncover the limb you see that several veins are manifestly distended; they are as full as though you had placed a ligature round the arm above the elbow, as we do in venesection.

Along with the four remarkable alterations in the condition of the part I have now mentioned, you will find that the function of the inflamed organ is suspended, or at least considerably impaired; that is, the person cannot move the limb without great pain; and when the inflammation has proceeded to its utmost extent, he is altogether incapable of using the affected

part. When the swelling and inflammation continue, and instead of being checked they increase, notwithstanding the means adopted to arrest them, you will then find other changes take place in the state of the part, and these of a very serious and important kind. All the symptoms that I have now described increase in severity; the part becomes greatly swollen; the redness is intense and vivid; and a most severe and agonizing pain is experienced, so as entirely to deprive the patient of rest.

The local action having reached to such an extent at some point that the part can no longer sustain it, that portion loses its vitality, and *mortification* ensues. The skin of the part assumes a dirty, turbid, or black appearance: it is, in fact, dead, mortified, or *gangrenous*. The part thus deprived of vitality is called *slough*. Under a less violent degree of inflammation, matter forms in the part; that is, a thick yellow or white fluid, which is technically called *pus*, is poured out by the inflamed vessels into the substance of the organ. Where it is effused into a spot, and we find a cavity filled with such fluid, the name *abscess* is given to it: this is technically termed *suppuration*. Inflammation, then, occasionally terminates in this way; but in other instances, without proceeding to such an extent as we have above described, the swelling of the part may diminish, the pain and redness may be speedily lessened, the symptoms of inflammation gradually disappear, and the natural state of the part return. It will then recover the power of exercising its proper functions. This is called *resolution*. Under certain circumstances (but not in the kind of inflammation we have now been considering) the symptoms will suddenly and almost immediately disappear; they will go away at once. This sudden disappearance has been designated by the French nosologists *delitescence*: this is derived from the Latin, *delitescere*—meaning, to be concealed or hidden; in fact, it would be equivalent in English to the expression *sudden disappearance*. In the resolution of inflammation there has been a swelling, that is, interstitial deposition, in the texture of the part, which is slowly removed: there is a gradual subsidence of the inflammatory symptoms, and the progress of this natural termination occupies a considerable time. The sudden and immediate removal of inflammation is a different occurrence from this, and I think there is propriety in distinguishing these two terminations from each other; viz. the sudden and immediate disappearance, or the *delitescence* of the French; and the slow removal of the disease, which we call in English *resolution*.

Now in any case in which mortification has occurred in a certain part of the inflamed

member, or in which suppuration may have taken place, you will find that in the neighbourhood of the mortification or of the suppuration, there is a considerable swelling, which is caused by an interstitial deposition of coagulable lymph around the part. After the process which the occurrence of suppuration renders necessary, is gone through, and indeed without this process, wherever thickening or induration does not subside when the inflammation has passed away, there remains a state of parts which, although not distinguished in our language by any particular term, has been alluded to by the French, under the name of *engorgement*. This hardness of the part, which is produced by the interstitial deposition, disappears again, in general, as the inflammation declines; but, in many instances, the function of the part may be seriously injured by it, although the inflammation has not proceeded so far as to cause the more serious changes of mortification and suppuration.

Such are the principal effects produced by inflammation in a part where it occurs: mortification, when in its utmost violence; suppuration and the formation of abscess, in a less severe degree; next interstitial deposition, and consequent enlargement and thickening, which impair the motion and more or less affect the function of the organ; and lastly, the gradual, slow subsidence of symptoms by resolution, or the sudden and immediate disappearance by delitescence.

These various effects usually are described as the *terminations* of inflammation; but this is not a very accurate expression, because in point of fact, the inflammation does not terminate with these occurrences. If mortification take place, or if abscess be formed, the inflammation is not at an end. The symptoms are in part relieved, the swelling is diminished, the pain and the heat are lessened, but the redness continues, with more or less of uneasiness, and it will be a long time before the part returns to its natural state. You can, therefore, by no means say that inflammation has terminated, when mortification and suppuration have taken place: they are parts of inflammation, not the conclusion of the process.

Such are the effects which inflammation produces in the part which is its immediate seat,—such are the primary or local results of this increased action; but we find, at the same time, that other effects are produced, belonging to the head of secondary, or sympathetic, disturbances—effects which, as they involve a considerable number of the organs of the body, have sometimes been called the *constitutional* symptoms of inflammation. We find, in the first place, that the vascular system is sympathetically disturbed—the action of the heart is augmented, and the pulse is full, strong, and frequent.

The nervous system also is deranged: there is pain of the head, as well as of the back and limbs; restlessness, want of sleep,—in some cases even delirium. The digestive organs are obviously and considerably disordered; there is a white tongue; want of appetite, thirst, sometimes even nausea and vomiting; costiveness. The various secretions are suspended, or diminished, and the skin is hot and dry. The mouth is parched; the urine is scanty, high-coloured, and turbid; and in all probability the secretion of the mucous membrane of the alimentary canal is considerably diminished: we may infer this from the obvious effects. These various circumstances taken together constitute the state of sympathetic inflammatory fever; that is, febrile disturbance, produced by local affections. The sympathetic disorder gradually declines, in proportion as the original local mischief becomes lessened. When this takes place, the secretions that have been previously suspended are restored; the circulation, which is relieved by these natural outlets, becomes tranquil; the nervous system is soothed, and appetite returns. Such are the several phenomena of a well-marked attack of inflammation. You observe there is a correspondence in character between the local and general disturbances: where there is a violent local disease, there is an equally severe general disturbance of the system.

We next come to inquire how the changes that I have mentioned in the part can be explained. It is very apparent, I think, from the circumstances already mentioned, that there is an increased quantity of blood sent to the inflamed part, and, also, that there is a greater quantity than natural circulating through it. The increased action or throbbing of the organ, locally; the visible distention of the great venous trunks; the fulness of the small vessels, which is proved by the redness, and the general congestion which we find in all the tissues of an inflamed part, sufficiently prove that there is an increased quantity of blood sent to it. On examination, we find that all the parts, all the textures of the inflamed member, are preternaturally red; they seem to contain a greater quantity of blood-vessels, and these of greater size than natural. This inference is corroborated by an experiment which Mr. John Hunter made on the ear of a rabbit; he excited inflammation of the part, and when it was fully developed, he killed the animal, and injected the arteries of the head; he found that, in the inflamed ear, the vessels were much larger in size and considerably greater in number than in the opposite ear. You will see this account in his work, called "Hunter on Inflammation and the Blood."

These circumstances prove, then, that there is an increased quantity of blood sent

to the inflamed part; but it does not follow from this, that there is a larger quantity circulating through it. A greater quantity of blood might be sent to the inflamed part, and it might, as some have supposed, become stagnant; a greater quantity might be conveyed to a vessel, and yet be prevented from passing through it. This is a notion that has been entertained by some pathologists who have attempted to defend it, but there are other circumstances which, to my mind, prove very clearly that there is not only a larger quantity sent to the part, but actually circulated through it. In the first place, if you make an incision into an inflamed part, you find a larger quantity of blood flows from it than from one that is sound. The phenomena of phlegmonous erysipelas prove this. If you make a cut through the integuments, in cases where the inflammation affects the skin and cellular membrane, you find, from such incision, an immense quantity of blood readily escapes; you observe that a greater number of small arteries bleed freely, and a larger effusion of blood takes place, than under other circumstances. If you perform an operation on an inflamed part (which you ought not to do), or in its immediate neighbourhood, you find a much greater number of vessels bleeding so as to require attention, than if you were cutting into a sound texture. The state of fulness in the vessels is a sufficient proof to me that a larger quantity of blood is circulated through them than in the natural state. If there were merely a larger quantity sent to the part, and it remained stagnant, you would not have the vessels distended; but if the hand and the fore-arm are inflamed, you will be struck with the considerable distention of the vessels. In such cases I have tried this experiment:—it being necessary to bleed an individual, in a case where the hand and fore-arm were inflamed, I had an opening made in each arm, and I found that within the same space of time, dividing the veins at the same moment, about three times more blood flowed from the vessel of the inflamed limb than from those of the sound side. This experiment I have repeated in several instances, and have always found the same result; so that I can have no hesitation in asserting that, in an inflamed part, there is both a larger quantity of blood sent to it, and a larger quantity circulating through it. Our general views of the subject, then, lead us to regard the phenomena of inflammation—that is, the changes which occur in the part itself, and constitute the local symptoms—as dependent upon an increased activity in the circulating system of the part. The redness and preternatural heat are obviously accounted for on the same principles. Both depend upon the increased quantity of blood in the parts. The heat

of the body certainly depends, in a great measure, on the peculiar change on the blood effected in the lungs; and when a larger supply of it is sent to a part, from whatever cause, it obviously follows that the temperature must thereby be increased. In conformity with this view, you find, as I have already intimated, that the temperature of the part never rises above that of the blood. The swelling is to be accounted for partly by the turgescence occasioned by the general distention of the blood-vessels, and partly by the interstitial depositions to which I have already alluded; and the pain will be readily explained by the circumstance of the nerves participating with the other textures in the vascular disturbance. It has been a disputed point whether the pressure of the turgid vessels upon the nerves caused the pain, or the irritation of the nerves gave rise to the vascular turgidity:—it is a question of little moment, and which scarcely admits of a positive answer.

With respect to the general symptoms, they are to be regarded as sympathetic effects, produced by the inflamed part on the several portions of the economy in which they occur; and here we see that the local disturbances act equally on the vascular and nervous systems as on those of digestion and secretion. Another view (and some of the phenomena would seem to justify the idea) is, that the sanguiferous system is, in the first instance, disturbed in consequence of the disorder in the vessels of the inflamed part being communicated to the rest of the vascular system, and thus producing the derangements in the secretive, digestive, and other systems. Both these explanations of the phenomena have been offered.

Having gone through these general views of the state called inflammation, and of the mode in which its obvious phenomena are to be explained, a further question arises respecting what has been called *the theory of inflammation*—that is, an attempt to determine the exact state of the minute vessels of the part which produces the different changes above-mentioned. Now, inflammation is so important a circumstance in the consideration of disease; so very large a portion of all the complaints that we have to treat, is of this nature, and the phenomena that accompany it are so striking, that you will not be surprised to learn that great attention has been paid to it, and many efforts made to trace the affection to its source. I am sorry to say that these have hitherto been unsuccessful. All that we can say of the seat of inflammation is, that there exists an increased activity of the vessels in the part; yet not a state of increased activity merely, but increased activity altered in its mode. In what that alteration

consists, we are unable to determine. It is not simply a state of increased activity, because if the vascular system of the hand were increased in its ordinary action, it might occasion increase in the bulk, but would not produce inflammation. There is an increase of activity, with a great deviation from the normal or healthy state; but we are not able to point out exactly in what the alteration consists. I have adverted to attempts that have been made to explain this on the principle of obstruction in the vessels. The idea of Boerhaave was, that the blood got into certain vessels, and could not pass through them: hence his notion of what he called *error loci*. The opinion of Cullen was, that a spasm took place in the vessels, which prevented the blood from being readily transmitted; this he supposed to be the state of the minute vessels while the action of those leading to them was increased. Others have conjectured that quite a different condition of the minute vessels was present—namely, a want of tone, or what was called *atony*. All these, however, seem to be nothing better than fanciful ideas—not grounded upon an acquaintance with disease. A great many inquirers have armed themselves with microscopes, and they have then excited the circulation in the skin of a transparent part, where the passage of the blood could be seen; in fact, they have attempted to create inflammation artificially, and to note the phenomena produced. But we may observe generally in regard to these investigations, that the different experimentalists have arrived at the most opposite conclusions: some have supposed inflammation to arise from increased activity of the vessels, and increased transmission of the blood; others, again, that there is an atony of the vessels, and obstruction to the passage of their contents. These contradictory results are equally said to have been deduced from direct observation by microscopic inquiry; we, therefore, can place little reliance on statements of this kind; and I must say, that so far as I know, investigations of this nature have not afforded us any real information on the subject of inflammation. We can see that inflammation has its seat in the vessels of the part, and this disordered action resides in the same vessels which carry on the healthy functions, the natural processes of secretion and excretion, and which perform all the active business of the animal economy in a healthy state. Now I may observe, that we do not at present understand what the modifications are in the actions of those vessels which produce the various results we witness in the different organs of the body: we do not know, for example, how it happens that the capillary vessels of one part deposit the substance of muscles; those of another part the substance of bone; of another, of fat; and so on. And as we cannot yet tell what

the difference is in the minute vessels that gives rise to such remarkable differences in the healthy products of their action; so we need not be surprised that we are not able to determine exactly in what the disturbance consists which constitutes the diseased state of inflammation.

[Mr. Lawrence here stated, that having proceeded thus far in describing the general state of inflammation, he would not this evening enter upon the particular parts of the subject; but having a few minutes to spare, he would advert briefly to two or three cases in the hospital, which illustrated some important practical points. These will be found among our Reports, under the head "St. Bartholomew's Hospital."]

OBSERVATIONS

ON THE

Nature of the Labours undertaken by

BARON HEURTELOUP,

FOR THE

IMPROVEMENT OF LITHOTRITY.

To the Editor of the London Medical Gazette.

SIR,

As Baron Heurteloup has allowed me to read the manuscript of a work on Lithotritry, which he is preparing for the press, and it will be some time before it can be published, I have availed myself of his permission to extract such observations as, in the meantime, I think most likely to afford information to your readers on this important subject. With this view, I have much pleasure in forwarding them to you for insertion in the Gazette.

I am, Sir,

Your obedient servant,

J. RUTHERFORD ALCOCK.

October 11, 1829.

From the danger and pain of the operation of lithotomy, scientific men for ages had endeavoured to find some milder means of relieving calculous patients. Chemistry and galvanism were tried in vain, and mechanical means were resorted to; but the only success that attended them was the partial relief of the patient. Some instruments destined to seize small stones lodged in the urethra were the only results. The endeavour by these means to withdraw stones from the bladder, when they were very small, sometimes

succeeded; but the idea of crushing stones, by instruments introduced through the natural passage, had not been put in execution. The belief which all surgeons entertained of the necessity of an instrument being curved, to enable it to be passed into the bladder, was a difficulty which baffled all their efforts; for it was impossible to develop an instrument with this curve that would destroy calculi, often voluminous and hard.

It was not, then, until it was proved that a straight sound, three or four lines in diameter, might be passed, that the attention of surgeons was more particularly and successfully directed to finding the means of breaking up stones in the bladder by an instrument passed through the urethra.

Many mechanical combinations formed upon this principle were the result of their labours; but of all these, two only have received the sanction of experience as fitted for practical purposes.

The one is that known by the name of "perce pierre," or "instrument à trois branches," which was the first employed; and the other is mine, noticed by the Institute, and in which I have endeavoured to obviate the defects of those which preceded them, in cases where the calculi were more than eight lines in diameter.

The art of curing calculous patients, like every other branch of the science, fell far short of perfection in the commencement, and could only be brought to that state by progressive steps of improvement; it was, therefore, not to be expected that the first instruments invented should be the most perfectly adapted to their end.

The means employed might appear very ingenious and satisfactory in the first case, and yet, even while admired, give rise to some ideas for their improvement, by the observation of defects or imperfections. Experience would necessarily suggest ameliorations in proportion as new indications were observed.

It was thus that, after having repeatedly employed the "perce pierre," I found that this instrument became insufficient in proportion as the stone increased in size, and that, to render lithotritry applicable to the majority of cases, it was necessary to devise means of breaking up the stones more promptly, and with less injury to the bladder.

A short description will enable my readers to appreciate the nature and end of the labours I thought it desirable to undertake, with a view to enlarge the limited resources of lithotritry.

The action of the three-branch instrument is limited to making a perforation each time the stone is seized of the diameter of the tube introduced in the urethra; this hole, then, can never be to the extent of the diameter of the stone when it exceeds ten or twelve lines.

It necessarily follows, that the calculus can only be broken after having frequently repeated these inefficient perforations, which can only be done by allowing the stone to fall to the bottom of the bladder, in order to re-seize it and present the stone in another position for the action of the perforator.

It will easily be seen, without bringing any proofs, how much this left to be desired, especially when it was required to break up a stone of a certain size; for, to effect this, it was necessary to seize the stone, in order to perforate it—to *release it*—*retake it*, to make a second hole, and renew this manœuvre until the body was broken. After this, each fragment *was again to be seized*, to submit it to the crushing process. The consideration of these steps certainly gives the idea that this instrument is tedious, and often painful in its application.

I have endeavoured to improve upon this, by means of my own peculiar combinations, and think I have succeeded in rendering that part of the operation which consists in breaking the stones as simple, prompt, and gentle as possible. The stone, seized without difficulty in the bladder, and strongly held, is perforated first by a head, which, at the first attack, makes a hole in the calculus four lines in diameter. This perforation is succeeded, without loosening the stone, by another stilet, adapted to the enlarging the hole already made. I thus excavate the calculus, the centre is reduced to powder, and the circumference falls into the bladder in the form of a shell, or excavated fragments.

If we consider that this result, (the breaking up of the stone, effected with the "*perce pierre*," after a great number of perforations,) is obtained with this system of excavation, by seizing the stone *once*, and submitting

it to the action of the instrument but *once*; that during the operation there is scarcely any movement of the instrument, and the breaking up of the stone takes place in a bladder filled with water previously injected, and which can be renewed at pleasure, the advantages resulting from the use of these instruments, in skilful hands, will be easily appreciated.

To these favourable circumstances must be added the position of the patient and the steadiness of the instrument, which I obtain by means of the little bed, or rather a kind of arm-chair, on which I place the patient, when the volume of the stone is such as to require the use of the excavating instruments. On this bed the patient is seated in a commodious situation, and the instrument grasping the stone is fixed in a kind of vice, which is either moveable or fixed, at pleasure; so that, while the operation is going on, the patient is perfectly unaware of what is passing; and this ought evidently to be the case, since the instrument does not move, the action of the stilet being within it, and in the middle of the water previously injected.

It was for the invention of this instrument for excavation that the "*encouragement*" was awarded to me two years ago, by the learned body which has since conferred upon me the great prize of surgery for the "*important improvements*" I had further effected in the art of lithotritry*.

This last improvement is the instrument I have called *brise-coque*, and which completes the set I have constructed in the intention of curing patients, by means of lithotritry, with the greatest possible chance of success. The operation of crushing the stone was certainly rendered less tedious and fatiguing by its excavation, thus breaking it up at the first attack;—but there was more yet to be done.

The result of the excavation I practised was the reducing the calculus to *shell* fragments, and powder, which last was immediately voided with the urine.

* This prize was awarded by the Institute of France, two years ago, upon the report made of Baron Heurteloup's instruments, by M. Magendie; in the name of the commission formed to decide on the prize of Medicine and Surgery, founded by M. de Montyon. The members of the commission were MM. Portal, Boyer, Chaptal, Dumeril, Dulong, Guylussac, De Clainville, F. Cuvier, and Magendie reporter.—(J. R. A.)

The fragments, though too large to pass by the urethra, were reduced to a state in which the slightest pressure would crush them. It became of importance to construct some means of promptly breaking these shells, against which the excavating instruments were useless.

I first endeavoured to make use of the three-branch instrument, and employed it in the termination of the first operations I performed; but I remarked that the action of this instrument was slow on stones when entire, and left much to be desired even in the destruction of fragments, especially those which were flat and excavated, resulting from the action of the "evidur."

I thought that if I had been forced, by the small diameter allowed for the instruments, to employ an excavating or progressive action, that, now I had only fragments to attack, I might, with advantage, change the system, and replace the slow and gradual action of a drill by the more prompt and energetic one of two branches moved by a peculiar mechanism, so as to break the fragments as soon as seized.

It was the instrument resulting from this that I called the *brise-coque*, as indicative of the use for which it was destined, and in which I have succeeded beyond my hopes in combining the necessary elements for the prompt and perfect destruction of the stones.

This instrument is, in effect, by the facility with which it is manœuvred, the rapidity and energy of its action, at the same time that its movements are gentle, far superior to the *perce pierre* for the destruction of small stones, or the fragments of large ones; for its action must necessarily very much abridge the number of sittings, and the fatigue of the patient; and, consequently, increase the chances of success.

If I have rendered these details sufficiently clear to be understood, it will be observed that I have much abridged the operation; since, 1st, in large stones I have substituted a system of excavation requiring only one attack, and therefore only one seizure of the stone for a system of repeated perforation which required several attacks and searches in the bladder. 2dly, when small stones were to be destroyed, or fragments of large ones, I have replaced the perforating by a grinding system, which, by its powerful action, reduces the stone to

powder much more quickly, and with less fatigue to the bladder.

Such are the modifications which I have introduced in the means for crushing calculi. It was necessary it should be distinctly understood in what these consisted, for they ought to materially change the general results of the operation; for where the three-branch instrument would fail, these instruments completely succeed, which has been already proved by cases.

I have thus, then, in augmenting the chances of cure by lithotrity, by adding to the powers of the instruments, diminished the number of cases which will require the operation of lithotomy. Let us hope that the time will come when the necessity of this operation will be entirely obviated, and when that disease which is with reason looked upon with dread, will become one of little consequence, and quite under the command of our curative means.

Explanation of the Cuts.

These figures shew the comparative action of the two systems for destroying a stone in the bladder; the first is that of repeated perforations, the second the excavation. With this view I have taken two stones which were removed from the bladder of a calculous patient by the operation of lithotomy some time ago.

These two calculi, exactly similar in size and hardness, appeared to me well adapted to shew distinctly the difference between the action of instruments which simply perforate and those which excavate. They were submitted to the action of the instruments in the bladder of a dead body: in the one I made ten perforations with the "perce pierre"; to the other I employed my instruments for excavation. The instruments employed on both stones were three lines and a half in diameter. The plates represent them in the state to which they were reduced by the action of the instruments. The great difference in the effect will be evident from a single glance.

The stone represented in the first three figs. was attacked by the "perce pierre," and though perforated in ten places, is still entire, and far from being in a state to break up. This, nevertheless, required the instrument to be opened

ten times, ten researches to be made, and the stone to be seized as often : it shews, at present, holes in which the branches of the instrument might easily be entangled ; as also in which the perforator might enter, and as often as this happens, its action must of course be unavailable ; and this must often take place. To perform these 10 perforations it required 58 minutes—nearly an hour, which gives some idea of the time that would necessarily be taken up in seizing and reducing all the fragments, even when broken, before they could pass the urethra.

I have only to compare these results with those obtained by the action of the "evidur," to convince every one of the immense advantages the latter must have. In 19 minutes the stone was reduced to a thin shell, easily broken and reduced to smaller morsels by the *brise-coque*. To effect this, I only required to seize the stone once, and instead of at the end of 58 minutes leaving a pierced, but entire, stone in the bladder, in 19 minutes there no longer re-

mained any thing but flat or concave fragments.

The remains of the stone which were found in the bladder of the subject, in the form of excavated fragments, have been accurately drawn. In order to make the excavating action more clearly understood, I have united the two largest fragments with a little gum, to give the concave form to the figure, necessary to make the mode of action more clearly understood. This will account for the line down the middle of the largest shell, in the second set of figures. The piece which has a spiral appearance, I call the base, and this round form is the impression of the instrument. When I began my lithotritic operations, I used to perforate the stone until this part flew out ; but I have since thought it better not to push the perforation so far, but to stop short when three lines from the extreme side or base of the stone, reserving this means to myself of more easily breaking the stone by the resistance of the base.

Action of the "Perce Pierre Vesicale" on a stone 15 lines in diameter, seized and perforated 10 times, and still

entire : it is presented in three aspects, in order to shew all the holes :—

The time occupied was 58 minutes.

Action of the "Evidur" instrument on a stone 15 lines in diameter, seized once, scooped out, and reduced to thin

shells : the different pieces found in the bladder are here represented :—

The time occupied was 19 minutes.

AN ESSAY
ON
ARTIFICIAL TEETH,

BY LEONARD KOECKER,
Surgeon-Dentist, Doctor in Medicine and Surgery.

It may be assumed as undeniable, that general surgery has at present almost attained the summit of perfection with regard to the restoration of some of the most essential parts of the human body by artificial means. Not only artificial limbs, such as arms and hands, legs and feet, but the most prominent, complicated, and delicate parts of the system, as the eyes, the nose, the chin, the lips, and even the tongue, may be rendered so complete an imitation of nature as to deceive, as it regards appearance, the nearest observer. Yet the utility of these parts is, and always will be, more or less imperfect, and little of the natural function of the artificial leg or arm, and still less of the eyes, nose, or tongue, and other artificial substitutes, can be obtained.

Artificial teeth, however, when judiciously and skilfully inserted, may be justly considered to afford greater advantages than all other mechanical substitutes in surgery. They may be rendered almost as useful as the natural teeth, and capable of assisting in mastication, as well as giving a natural appearance to the face, and the power of a distinct and harmonious pronunciation.

It must, however, be considered at the same time, that the obtaining of this degree of utility by art, is not to be acquired without skill; indeed, the insertion of artificial teeth can be properly performed only by means of a comprehensive knowledge of the anatomy and physiology of the teeth, and all the parts connected with them, as well as a minute acquaintance with all their diseases.

The manufacturing of artificial teeth, therefore, cannot be left with safety to the artizan alone, however great his mechanical skill may be, like that of an artificial leg or arm, or even of the eyes, &c. yet this idea is as commonly received at present as it is erroneous and absurd.

So great, indeed, did I find the difficulty of obtaining any useful assistance from the mechanical dentist in America, that, during the whole of my

practice in that country, I was compelled to attend to this laborious branch of the art myself, as well as to the surgical treatment; and, I believe, it is principally in London and Paris, and a few other large European capitals, that the scientific dentist may receive some useful assistance from the mechanic.

Still, even with such assistance, the conscientious dentist will be compelled to add much time and labour to that of the best mechanic, if it be his determination to insert such artificial teeth only as are sufficiently *useful*, as well as permanently *harmless*, to the remaining teeth, and other parts with which they are connected.

Dental surgery, as a branch of the healing art, is yet a very obscure science, and, at all events, not less intricate than any other of its branches. It is of all others the least understood by medical men, as well as by the public at large, and hence the backwardness in drawing a just distinction between the mechanical and the scientific dentist, although there is in reality as great a difference between them as there is between the unpretending surgical instrument-maker who manufactures the artificial limb, and the surgeon whose duty it has been to amputate it.

If the facts just stated are duly considered, we can no longer be surprised at the frequent occurrence of individuals, even of the most exalted station, so much mistaken as to apply to the mechanical dentist for the insertion of artificial teeth, at a period when the various diseases of their mouths require surgical treatment. This sufficiently accounts for the frequent loss of all the natural teeth, after the insertion of a few artificial ones.

The following case is at once a very complete illustration of the pernicious consequences resulting from the injudicious employment of artificial teeth, and of their excellent effects when applied with judgment.

Mr. —, of —, requested my professional assistance in the year 1820; his age was about 55, his constitution delicate, and suffering greatly from an injudicious treatment of his teeth, which he had received at various periods. According to the patient's own account, in consequence of the insertion of a few artificial teeth at an early period of life, and a constant neglect of his own, he had successively found himself compelled

to increase the number of artificial teeth, until, in a period of from ten to fifteen years, all his own teeth had been lost.

He had first two artificial teeth inserted with pivots upon the roots of two incisors; in a few years afterwards he required the use of another, and in a short time the fourth incisor and two cuspid teeth were lost, and replaced in the same manner.

The diseases of his teeth now rapidly increased; his gums became very sore and inflamed, and some of the roots of his incisors became unfit to hold the artificial teeth. The mode of insertion was, therefore, changed to the use of ligatures and ill-contrived springs, &c. and from the mechanical pressure of these means he was gradually losing his natural, and constantly compelled to increase his artificial teeth, until at last he became convinced of the destructive effects which this state was producing upon his health, which induced him to insist upon the removal of all the dead roots and stumps, and the few remaining roots or painful grinders, notwithstanding the opposition of his dentist.

During and after the loss of his own, several double artificial sets of teeth had been successively prepared, but they were so ill made as to keep his mouth constantly sore, and not only greatly to affect his speech, but also his mastication.

The teeth of this gentleman were objects of the greatest importance to him, not less from the circumstance of his being a public speaker, than from the inroads which had been made upon his health and spirits.

A new set of artificial teeth for the upper and under jaw was now prepared, which fitted him perfectly, by which simple means all his sufferings were removed.

Difficulties accompanying the Insertion of Artificial Teeth.

In most instances, no sooner is a tooth of some importance to appearance lost, than the restoration of such a defect by mechanical means is considered an object of the highest moment, without the least attention being paid to the remaining teeth and gums, which are either primarily or secondarily affected by the general morbid state of the mouth.

We look in vain for any information in those standard works which can be

justly deemed capable of giving any scientific information on this important subject; and, I believe, very little essentially useful has been written on this part of dentistry. The celebrated John Hunter, in his "Natural History of the Human Teeth," &c. has not investigated the subject of the mechanical part of dental surgery, and, with respect to the restoration of lost teeth, he confines himself to the transplanting living and dead teeth from the mouth of one individual to that of another. This practice is far more dangerous than the insertion of any kind of artificial teeth: it is happily at present erased from the list of surgical treatment, and abandoned by every surgeon of judgment and integrity. It needs, therefore, no further refutation.

I, nevertheless, saw this treatment revived by a dentist in Philadelphia, in 1818; and in four cases, in which I was subsequently consulted, I had sufficient opportunity of observing the extensive ravages produced by this operation, not only upon all the remaining teeth and the parts connected with them, but also upon the general health of the victims. I shall, however, not extend this essay by a minute detail of these cases, but beg only to refer the reader to a very distressing case of the transplanting of one tooth, which occasioned the most appalling and painful destruction of an amiable young lady, related in "The Medical Transactions of the College of Physicians of London," vol. iii. pp. 325, 338. This one instance is quite sufficient to illustrate the above statement, and to prove the dangerous and fatal effects that almost invariably must follow this practice.

Mr. Joseph Fox, in his excellent work on "The Natural History and Diseases of the Human Teeth," says very little on artificial teeth; but so far as he dwells on the theory and practice of the subject, he sufficiently evinces that his investigation of the mechanical part of dentistry is founded on very general views, and I am not acquainted with any other English author who has sufficiently treated on this part to deserve the particular attention of his readers.

Among the continental authors, may be noticed Angerman, Plaff, Tourdan and Maggio, Bourdet, Folauchard, Gariot, Laforgue, and, lastly, Dr. De-

labarre. Of these, the last has, I believe, treated more extensively on the subject than any other dental writer. His "*Traité de la Partie Mécanique de l'Art du Chirurgien Dentiste*," in two volumes, accompanied with forty-two plates, is exclusively devoted to the mechanical part of dentistry.

But, although Dr. Delabarre is very deserving of the gratitude of the manufacturers of artificial teeth, for the great patience and research, by which he has endeavoured to facilitate their labours, still he has, like all other authors who have preceded him, dwelt very little on the surgical principles under which the different artificial preparations should be adopted; although it cannot be denied that the merits and demerits of all the methods of inserting artificial teeth which he describes, and with other authors recommends, must be entirely dependent on the principles under which they are applied.

Having, in the preceding pages, stated very generally the great advantages to be derived from artificial teeth, when applied with skill, as well as their injurious consequences if inserted without the necessary judgment, I now beg to make a few more particular remarks on those modes and malpractices which ought to be rejected, and to state, at the same time, the principles by which I have been guided in the mechanical part of my practice.

During the greater part of my residence in America I was obliged to unite the entire duty of the mechanical part of my profession with that of the surgical treatment of all the diseases of the mouth; and in a country which, above all others, offers the best school for the practical surgeon dentist. I have, therefore, both from necessity and opportunity, bestowed much attention upon this branch, more especially in all its bearings with curative and preventive treatment. I hope that, in laying before the profession the principles which I have adopted in my own practice for many years, I may not be altogether unsuccessful in rendering myself useful to my brethren.

In forming proper rules for this mechanical part of surgery, it will therefore be best, for the sake of distinction, to take into particular consideration, first, such treatment and practice as is injurious, as well as such as is proper and necessary; secondly, all those circumstances

which are either indicative or contra-indicative of the use of artificial teeth; and, thirdly, such modes of manufacturing and inserting artificial teeth as must be considered either positively or negatively bad, as well as those which are most useful and effective.

Of the Treatment of the Mouth previous to the Insertion of Artificial Teeth.

It must be perfectly evident to every surgeon, that, in a diseased state of the mouth, or its individual parts, as the jaws, sockets, periosteum, gums, or the remaining teeth, the unavoidable bearing of the artificial apparatus cannot be supported without great loss of health, and even gradual destruction of those parts to which the artificial teeth are affixed.

Whether the morbid state of these structures be founded on natural causes only or on the omission of surgical treatment, or whether it be partly aggravated and produced by injudicious treatment, matters very little in point of fact, although the degree of disease must greatly differ, and be much more extensive and complicated, under the latter than under the former circumstances. I have more minutely pointed out those modes of surgical treatment which I deem improper, in my "*Principles of Dental Surgery*;" and I have only to add, therefore, that, in every instance, by the application of artificial teeth, the pernicious effects of such modes are considerably aggravated; and that, under such injudicious treatment, the artificial teeth are rendered an additional exciting cause of all the diseases already affecting the mouth. Such, however, is the propensity of the public to take an erroneous view of the subject, that it generally requires the greatest persuasion to dispose the patient to submit to a proper and permanently useful treatment, while almost invariably he wishes, and not unfrequently persists, in desiring the adoption of such mal-treatment. Should the dentist yield to his request, the patient has one or two artificial teeth inserted, and, from refusing to submit to the treatment indicated by the state of his mouth, his teeth are gradually destroyed, until a whole artificial set becomes requisite, as in Case, No. 1. The injurious results of this practice are perfectly apparent, not only to the

surgeon, but to any one of common sense, by the following considerations. There is, perhaps, not one case in a hundred requiring artificial teeth, in which the other teeth are not more or less diseased, and the gums and alveoli also either primarily or secondarily affected. The mechanical and chemical bearing of the artificial teeth upon such diseased structures, naturally becomes a very powerful aggravating cause of the disease, even if they are well contrived and inserted; if, however, they are not well constructed, and are inserted with undue means or force, or held by too great or irregular pressure, or by ligatures, or other pernicious means for their attachment, the morbid effect is still more aggravated, and a general state of inflammation in the gums and sockets, and particularly in the periosteum, very rapidly follows. The patient, moreover, finds it impossible to preserve the cleanliness of his mouth; and his natural teeth, as well as the artificial apparatus, in combination with the diseases of the other structures, become a source of pain and trouble, and the whole mouth is rendered highly offensive and disgusting to the patient himself as well as to others. Indeed, that such is the fact I may confidently appeal to almost every individual who is now wearing a considerable number or a whole set of artificial teeth.

Thus, by the improper insertion of artificial teeth, the patient not only loses all the good effects of this treatment, but also his own remaining teeth, exposing himself for a considerable period to all the consequent diseases of the mouth, as well as of the constitution; whereas, by a proper treatment, the whole mouth would have been rendered and preserved perfectly healthy, the further loss of teeth would have been almost completely prevented, and the defect so restored as to prevent the necessity of increasing the number of artificial teeth for many years, or perhaps during life.

The too early insertion of artificial teeth after the surgical treatment of the mouth is completed, is also a consideration of no small importance, though too often entirely neglected. Indeed, even after the most judicious treatment of the mouth has been instituted, artificial teeth may be rendered a source of irritation and injury, if applied before

nature has perfectly produced those changes which always follow the extraction of teeth by means of absorption in the sockets and gums; and producing immediate inflammation in the parts not yet perfectly recovered, and soon losing their adaptation to the form of the gums, they must become the cause of constant irritation. Convinced of the truth of the above statement, I have made it an invariable rule during my practice in the application of artificial preparations, to bestow every necessary surgical attention upon each individual part of the mouth which the case required, so as to render the jaws, the gums, sockets, periosteum, and every tooth perfectly free from disease.

[To be continued.]

PECULIAR CEREBRAL AFFECTION IN CHILDREN.

*To the Editor of the London Medical
Gazette.*

SIR,

If you should have a niche in an early number of the Medical Gazette, which you do not know how to fill up in a more profitable way, you may insert the following reply to your correspondent, W. H.*

And, first, let me remark, that if I have had any satisfaction in having published my remarks upon "An Affection of Infancy resembling Hydrancephalus, but arising from Exhaustion," it has chiefly been that it has led to my name having so frequently appeared upon the same page with that of Dr. Gooch. Your correspondent attempts to establish a difference of opinion between Dr. Gooch and myself, inasmuch as I have ascribed the effusion into the ventricles of the brain in cases of exhaustion to congestion of that organ, whilst Dr. Gooch attributes it to an empty state of the cerebral vessels; and he considers that this remark of Dr. Gooch is the most valuable part of the inquiry. He never seems to have suspected that the question may not be fully determined.

I would beg, therefore, just to refer this gentleman to Dr. Kellie's well-known paper, in the first volume of the

* See Medical Gazette, No. 98, p. 84.

Medico-Chirurgical Society of Edinburgh, for a rather full and most interesting inquiry upon this very point. He will there learn that it is a question not quite so easily determined—not quite so perfectly decided as he seems to imagine.

Your correspondent mentions the name of Dr. Abercrombie in such a manner as to leave it probable that I was anticipated in my views of this affection by that gentleman. If your readers will refer to my little essay, they will see that Dr. Abercrombie, as well as Dr. Gooch, were anticipated by me by several years.

I may add that I have very recently witnessed a most interesting case of the affection in question, in consultation with Dr. James Johnson and Mr. Balderson, of Poland-Street, Oxford-Street. The causes, the course, the symptoms, and the remedies, were precisely such as I have pointed out, and the event was such as fully to satisfy us with the propriety and efficacy of the plan of treatment pursued. I am, Sir,

Your obedient servant,
MARSHALL HALL.

London, Oct. 18, 1829.

CYST IN THE ORBIT, OBEYING THE INFLUENCE OF THE MUSCLES.

To the Editor of the London Medical Gazette.

SIR,

IN the second volume of the *Chirurgie Clinique de Montpellier*, Professor Delpech has given a narrative of an extraordinary disorder,—a cyst, which filled the orbit, having annihilated the globe of the eye, and being itself obedient to the muscles which move the ball. The professor deserves the praise for candour, in having given us the history, since his treatment of the malady proved fatal to the patient. The case in the original language is diffusely related; but I have endeavoured so to contract the statement as to omit no sentences which contain practical points. As it appears to be the order of the day in France to publish the pathological history of every man, woman, and child, who dies, it is much to be wished that all irrelevant

matter should be foregone. Men in practice have not a superfluity of leisure for reading. There is a maxim, with which one of our profession prefaced a book, and which should be more impressed on the French medical writers, who make such exorbitant claims on the time of professional readers—"Life is short."

I am, Sir,

Your humble servant,

ROBERT HULL.

Norwich, Sept. 18, 1829.

An Account of a Cyst developed in the Orbit, and prolonged into the Cranial Cavity through the Foramen Opticum.

Louis Bonnet, aged 20 years, enjoying tolerable health, was admitted to the Hospital Saint-Eloi, April 30, 1825. He had, ever since he was eight years old, a considerable tumor, which filled the left orbit, and projected greatly between the eyelids. Upon attentive examination the following were the appearances:—The lids tightened, very distended as to breadth, were separated from each other by an interval of one inch and a half; their skin thin, injected. The intermediate space was convex, projecting, red, covered with a conjunctiva very vascular, fungous, bedewed with tears and puriform mucus. The spot wherein the cornea should have existed, presented scarcely any traces thereof: a brownish tinge was the only mark. The sight had been lost many years, and the eye seemed wasted. The projecting mass appeared to be composed of a tumor placed betwixt the muscles of the eyeball, which moved it, and whose resistance announced a cyst. The tumor fluctuated throughout its extent.

The patient remembered that, at its commencement, he felt a pain rather sharp, for about a month, in the depth of the orbit; that, soon after, the eye seemed lifted, and eventually driven from its cavity, the vision failing proportionally; that ulcerations attacked the cornea, perforated it, and evacuated the vitreous humour.

It was evident that the orbital cavity had acquired extraordinary dimensions. The right eye, the other senses, the intellect, were unchanged. There was no head-ache: the patient was harassed by his malady, because the least variation of atmosphere renewed the inflammation and ulcerations of the conjunc-

tiva. An operation was decided on, with the consent of the patient.

6th May.—We plunged horizontally the blade of a straight bistoury towards the middle of the lower lid, where the tumor seemed most to fluctuate. A transparent, citron-coloured fluid, was spirted out with great force. We were surprised at the quantity; and still more astonished when, introducing a finger into the cavity, we discovered that the cyst was not confined to the orbit, which, however, it entirely lined; but that it was prolonged into the cranial cavity, through the foramen opticum, which was so dilated as to give free passage to the forefinger. The posterior prolongation of the cyst was plunged into the cerebral substance, whose consistence was easily distinguished (!!!). Charpie was introduced lightly into the cavity, and the borders of the wound were parted with a strip of anointed linen.

The patient suffered little the two first days; but, on the third, pains supervened, extending from the wound to the occiput. The features of the patient were profoundly altered; the tongue was red, thirst urgent, the temperature of the body much augmented, the pulse frequent, “*vif et sans consistance.*” Venesection ad $\frac{3}{4}$ x; “*cau de veau nitrée,*” &c. &c. The night was agitated; and there was delirium.

The fourth day.—Pulse quicker, &c. &c. Twenty leeches to each temple. The night less agitated. Stupor.

Fifth day.—Stupor more profound; cognizance quite lost. The legs and thighs were blistered; but death took place in the evening.

Autopsia 18 hours after Death.—Exterior of the cranium and vessels of the brain much injected. Sub-arachnoid cellular tissue infiltrated, semi-opaque, opalized. About three ounces of milk-like serum in the lateral ventricles. A softening of the brain throughout nearly the whole anterior left lobe, approaching to purulence; true pus furnished by the meninges.

A prolongation of the cyst had plunged into the substance of the inferior portion of the left lobe, about three inches of depth, thrusting before it the pia-mater and arachnoid. The cavity of this process contained purulent matter, as did the orbitar portion.

The optic foramen, situated higher

and more backward than its fellow, presented a diameter of more than six lines. The optic nerve had totally disappeared.

In the substance of the *right* anterior lobe of the cerebrum, in a parallel spot below, was another sero-mucous cyst, plunged in the cerebral substance, not pushing back the membranes: it was united to these in a solitary point below and before. It was as big as half a pigeon's egg.

If we admit that the cyst (the left cyst) originated in the foramen opticum itself, this hypothesis will explain all the phenomena.

We see, moreover, that we cannot be sure that such growths are not prolonged into the cranial cavity, because there exists no lesion of the cerebral functions. Must we then abstain from curative attempts in analogous cases? We think otherwise. We think we may succeed in distinguishing those cysts which penetrate within the cranium from such as are confined to the orbit. We think, also, that, in case of a false diagnosis, we may prevent awkward consequences by attention to the following rules:—A puncture with a flat trochar is a mode of exploration entirely innocent, by which we may learn the character of a tumor and of its contents. In a case similar to this, and whilst the fluid is escaping, we may convey into the cavity a soft bougie: this instrument will easily reveal if any danger is attached to further operation. If the extension of the disorder into the cranium be recognized, nothing remains but to withdraw the canula, and leave things to nature: the punctured part heals.

When a case similar to this has not been recognized, until an incision has been made, adhesive straps would suffice to connect the cut edges of the skin, and effect a reunion; but if it be necessary, if we could not otherwise prevent the entrance of air and consequent inflammation, we should not hesitate to employ suture; only it would be specially important to include in the suture integument alone, avoiding the cyst.

CARBONATE OF IRON.

To the Editor of the London Medical Gazette.

Uttoxeter, October 4, 1829.

SIR,

IN the Medical Gazette of Sept. 26th, Dr. Belcombe calls "the attention of the profession to the use of the subcarbonate of iron in chronic rheumatism," and, in concluding his communication, remarks, that "this remedy is only slightly mentioned by Dr. Scudamore, and not at all, as far as he is aware, by other writers."

It may, therefore, be presumed that the Edinburgh Medical and Surgical Journal does not come under Dr. Belcombe's notice; otherwise, he must have been aware of the following passage, occurring in a Report of the Diseases of Birmingham, published in the number of that journal for October, 1823, by my zealous and talented friend, Dr. Darwall, which corroborates, I may say anticipates, his observations:—

"It has been insinuated by some of the journalists, that amidst the numerous successful cases published by Mr. Hutchinson, other diseases may have been mistaken for it (neuralgia). However this may be, several opportunities have been afforded me of proving that the efficacy of the carbonate of iron, in relieving pain, is not confined to that complaint. A case of regular intermittent hemicrania was entirely cured by it, and much relief was conferred upon a case of syphilitic rheumatism, in which the pains came on most severely in an evening. Great alleviation also was effected in an instance of rheumatic gout of long standing, in which the joints were red and swelled. The visible effect upon the digestive organs was similar; great improvement in the appetite and spirits. In one case, accompanied with hysteria, the nervous symptoms and the pain vanished together."

If I mistake not, cases of the above description were communicated by Dr. Darwall to Mr. Hutchinson, and were published, about the same period, by the latter gentleman, in one of the London journals. To Dr. Darwall, therefore, belongs any merit there may be in first "endeavouring to extend the

use of carbonate of iron to other painful disorders."

I have the honour to be, Sir,

Your obedient servant,

ALEX. G. KENNEDY, M.D.

DIVISIONS IN THE HEALING ART.

[THE subjoined letter was inclosed in a note, in which the writer states his belief that it contains nothing offensive; and the one that follows it was accompanied by a request that it might not be inserted if we thought it likely to hurt Mr. Lawrence's feelings. We think it would be paying that gentleman a bad compliment to suppose that he could be "hurt" by either of them.]

To the Editor of the London Medical Gazette.

SIR,

ALLOW me to make a few remarks on a part of Mr. Lawrence's Introductory Lecture, attributing the division between medicine and surgery to monkish darkness and ecclesiastical ignorance. The decree of the Council of Trent, which is quoted, merely renewed a distinction which had existed before—a distinction which medical men had adopted for its usefulness, and continued for their own convenience; at least there could be no other reason for its continuance. In rude and barbarous ages, our whole art was merely operative surgery, and consisted in curing the wounds and bruises received in battle, or sustained by accident. Homer tells us that Podalirius and Machaon were skilful physicians—*ἰητῆς ἀγαθοί*; but proceeds to inform us that their whole employment was

Ἴους τ' ἐκταλινεῖν, ἐπὶ τ' ἥπια φάρμακα παρσσειν—

"to cut out the arrows, and to spread over the wound the soothing salve." They made no attempt to stop the progress of the plague, which ravaged their forces.

But, with the advance of civilization and the march of intellect, Celsus tells us there came in a host of diseases, unknown to the temperate and hardy savage. Then

*Macies et nova febrilium
Terris incubuit cohors.*

It was then this division arose; not arbitrarily enforced by acts of parliament,

or imposed at the will of colleges, but suggested by common sense: necessity gave a hint that, as there was so much to learn, it would be better to learn one part thoroughly than the whole cursorily. So, at least, I think we may infer from Celsus. At the very beginning of his first book, we find—"Post quem (Hippocratem scilicet) Diocles Carystius deinde Praxagoras et Chrysippus tum Herophilus et Erasistratus, sic artem hanc exercuerunt ut etiam in diversas curandi vias processerint. Iisdemque tempori in tres partes medicina diducta est," &c. Does not this imply that Diocles and the rest practised the art in such a manner that each took a separate department, and so medicine was *diducta*—was drawn asunder into three divisions?

But if this passage does not bear me out, turn to the beginning of the seventh book. "Hæc autem pars (~~que~~ manu curat) cum sit vetustissima, magis tamen ab illo parente omnis medicinæ Hippocrate, quam a prioribus exulta est: deinde, post quam *diducta ab aliis habere professores suos* cœpit, in ~~Egypto~~ *Egypto* quoque increvit, Philoxeno maxime auctore, qui pluribus voluminibus hanc partem diligentissime comprehendit. Gorgias quoque et Sostrates. . . . *Multique alii celebres viri singuli quædam reppererunt. Hac Romæ quoque non mediocres professores,*" &c. &c. Surely we learn from this, not only that many volumes were written on surgery at Alexandria, but also that it was practised as a *separate art*, by eminent men, both in that city and in Rome.

But what end does this argumentation answer? Are our abilities so cribbed, cabined, and confined, by the narrow limits of our profession, that we have not each scope enough for our researches? Is there no nook, cranny, or corner, in the undoubted department of the surgeon, which needs research? Is there no fact in physic which needs confirmation, no cloud of error or mist of prejudice which needs dispelling? Truly, when there is not, it will be time enough to dispute about our respective limits; but as things are at present, we had better, perhaps,

First lay this Anglers level with the ground,
Then, after, fight who shall be king of it.

There is a large field for each of us, without approaching the disputed confines; there is quite as much to learn as

will afford ample employment during the years generally allotted to education; and this is what must be considered in speaking to pupils.

Mr. Lawrence himself sanctions some division of this sort, which he elsewhere characterizes as absurd; saying, "Proceeding in *natural* order, you will attend, in the first place, to external diseases; after which, you will proceed to study internal affections." This division, then, cannot be very absurd, if it be natural and useful, though only for learners. Celsus speaks very sensibly on this same subject—"Illud autem omnia scire convenit, quod omnes medicinæ partes ita innexæ sunt, ut ex toto separari non possint; sed ab eo nomen trahant, a quo plurimum petunt."

To this we may all subscribe: granting there be no natural law enforcing the division between medicine and surgery, yet if this division were first made for convenience, and continued for its usefulness—if it be proper for learners—if each department contain as much as can thoroughly be learned in our years of education—then it cannot be very absurd, and should not be hastily attacked. There is no natural division between the jejunum and ileum; yet anatomists have found such division useful, and authorized our continuing it. England is divided in many places from Scotland and Wales, merely by an imaginary line, and yet geographers find such division useful, and continue it, though we are now one people; and if three persons were appointed to learn minutely, in a given time, the geography, productions, &c. of our island, they would act more wisely by making some such division, and communicating to each other the results of their inquiries, than if, acting without concert, each were to attempt the whole work.

I have the honour to be, Sir,
Your very obedient servant,
REGINENAS.

October 10th.

THE MEDICAL MILLENNIUM.

To the Editor of the London Medical Gazette.

SIR,

THE universality and versatility of Mr. Lawrence's genius, have been the subjects of various remarks during a very

AN ESSAY
ON
ARTIFICIAL TEETH,

By LEONARD KOECKER,

Surgeon-Dentist, Doctor in Medicine and Surgery.

It may be assumed as undeniable, that general surgery has at present almost attained the summit of perfection with regard to the restoration of some of the most essential parts of the human body by artificial means. Not only artificial limbs, such as arms and hands, legs and feet, but the most prominent, complicated, and delicate parts of the system, as the eyes, the nose, the chin, the lips, and even the tongue, may be rendered so complete an imitation of nature as to deceive, as it regards appearance, the nearest observer. Yet the utility of these parts is, and always will be, more or less imperfect, and little of the natural function of the artificial leg or arm, and still less of the eyes, nose, or tongue, and other artificial substitutes, can be obtained.

Artificial teeth, however, when judiciously and skilfully inserted, may be justly considered to afford greater advantages than all other mechanical substitutes in surgery. They may be rendered almost as useful as the natural teeth, and capable of assisting in mastication, as well as giving a natural appearance to the face, and the power of a distinct and harmonious pronunciation.

It must, however, be considered at the same time, that the obtaining of this degree of utility by art, is not to be acquired without skill; indeed, the insertion of artificial teeth can be properly performed only by means of a comprehensive knowledge of the anatomy and physiology of the teeth, and all the parts connected with them, as well as a minute acquaintance with all their diseases.

The manufacturing of artificial teeth, therefore, cannot be left with safety to the artizan alone, however great his mechanical skill may be, like that of an artificial leg or arm, or even of the eyes, &c. yet this idea is as commonly received at present as it is erroneous and absurd.

So great, indeed, did I find the difficulty of obtaining any useful assistance from the mechanical dentist in America, that, during the whole of my

practice in that country, I was compelled to attend to this laborious branch of the art myself, as well as to the surgical treatment; and, I believe, it is principally in London and Paris, and a few other large European capitals, that the scientific dentist may receive some useful assistance from the mechanic.

Still, even with such assistance, the conscientious dentist will be compelled to add much time and labour to that of the best mechanic, if it be his determination to insert such artificial teeth only as are sufficiently *useful*, as well as permanently *harmless*, to the remaining teeth, and other parts with which they are connected.

Dental surgery, as a branch of the healing art, is yet a very obscure science, and, at all events, not less intricate than any other of its branches. It is of all others the least understood by medical men, as well as by the public at large, and hence the backwardness in drawing a just distinction between the mechanical and the scientific dentist, although there is in reality as great a difference between them as there is between the unpretending surgical instrument-maker who manufactures the artificial limb, and the surgeon whose duty it has been to amputate it.

If the facts just stated are duly considered, we can no longer be surprised at the frequent occurrence of individuals, even of the most exalted station, so much mistaken as to apply to the mechanical dentist for the insertion of artificial teeth, at a period when the various diseases of their mouths require surgical treatment. This sufficiently accounts for the frequent loss of all the natural teeth, after the insertion of a few artificial ones.

The following case is at once a very complete illustration of the pernicious consequences resulting from the injudicious employment of artificial teeth, and of their excellent effects when applied with judgment.

Mr. —, of —, requested my professional assistance in the year 1820; his age was about 55, his constitution delicate, and suffering greatly from an injudicious treatment of his teeth, which he had received at various periods. According to the patient's own account, in consequence of the insertion of a few artificial teeth at an early period of life, and a constant neglect of his own, he had successively found himself compelled

to increase the number of artificial teeth, until, in a period of from ten to fifteen years, all his own teeth had been lost.

He had first two artificial teeth inserted with pivots upon the roots of two incisors; in a few years afterwards he required the use of another, and in a short time the fourth incisor and two cuspid teeth were lost, and replaced in the same manner.

The diseases of his teeth now rapidly increased; his gums became very sore and inflamed, and some of the roots of his incisors became unfit to hold the artificial teeth. The mode of insertion was, therefore, changed to the use of ligatures and ill-contrived springs, &c. and from the mechanical pressure of these means he was gradually losing his natural, and constantly compelled to increase his artificial teeth, until at last he became convinced of the destructive effects which this state was producing upon his health, which induced him to insist upon the removal of all the dead roots and stumps, and the few remaining roots or painful grinders, notwithstanding the opposition of his dentist.

During and after the loss of his own, several double artificial sets of teeth had been successively prepared, but they were so ill made as to keep his mouth constantly sore, and not only greatly to affect his speech, but also his mastication.

The teeth of this gentleman were objects of the greatest importance to him, not less from the circumstance of his being a public speaker, than from the inroads which had been made upon his health and spirits.

A new set of artificial teeth for the upper and under jaw was now prepared, which fitted him perfectly, by which simple means all his sufferings were removed.

Difficulties accompanying the Insertion of Artificial Teeth.

In most instances, no sooner is a tooth of some importance to appearance lost, than the restoration of such a defect by mechanical means is considered an object of the highest moment, without the least attention being paid to the remaining teeth and gums, which are either primarily or secondarily affected by the general morbid state of the mouth.

We look in vain for any information in those standard works which can be

justly deemed capable of giving any scientific information on this important subject; and, I believe, very little essentially useful has been written on this part of dentistry. The celebrated John Hunter, in his "Natural History of the Human Teeth," &c. has not investigated the subject of the mechanical part of dental surgery, and, with respect to the restoration of lost teeth, he confines himself to the transplanting living and dead teeth from the mouth of one individual to that of another. This practice is far more dangerous than the insertion of any kind of artificial teeth: it is happily at present erased from the list of surgical treatment, and abandoned by every surgeon of judgment and integrity. It needs, therefore, no further refutation.

I, nevertheless, saw this treatment revived by a dentist in Philadelphia, in 1818; and in four cases, in which I was subsequently consulted, I had sufficient opportunity of observing the extensive ravages produced by this operation, not only upon all the remaining teeth and the parts connected with them, but also upon the general health of the victims. I shall, however, not extend this essay by a minute detail of these cases, but beg only to refer the reader to a very distressing case of the transplanting of one tooth, which occasioned the most appalling and painful destruction of an amiable young lady, related in "The Medical Transactions of the College of Physicians of London," vol. iii. pp. 325, 338. This one instance is quite sufficient to illustrate the above statement, and to prove the dangerous and fatal effects that almost invariably must follow this practice.

Mr. Joseph Fox, in his excellent work on "The Natural History and Diseases of the Human Teeth," says very little on artificial teeth; but so far as he dwells on the theory and practice of the subject, he sufficiently evinces that his investigation of the mechanical part of dentistry is founded on very general views, and I am not acquainted with any other English author who has sufficiently treated on this part to deserve the particular attention of his readers.

Among the continental authors, may be noticed Angerman, Plaff, Tourdan and Maggio, Bourdet, Folauchard, Gariot, Laforgue, and, lastly, Dr. De-

AN ESSAY
ON
ARTIFICIAL TEETH,

BY LEONARD KOECKER,
Surgeon-Dentist, Doctor in Medicine and Surgery.

It may be assumed as undeniable, that general surgery has at present almost attained the summit of perfection with regard to the restoration of some of the most essential parts of the human body by artificial means. Not only artificial limbs, such as arms and hands, legs and feet, but the most prominent, complicated, and delicate parts of the system, as the eyes, the nose, the chin, the lips, and even the tongue, may be rendered so complete an imitation of nature as to deceive, as it regards appearance, the nearest observer. Yet the utility of these parts is, and always will be, more or less imperfect, and little of the natural function of the artificial leg or arm, and still less of the eyes, nose, or tongue, and other artificial substitutes, can be obtained.

Artificial teeth, however, when judiciously and skilfully inserted, may be justly considered to afford greater advantages than all other mechanical substitutes in surgery. They may be rendered almost as useful as the natural teeth, and capable of assisting in mastication, as well as giving a natural appearance to the face, and the power of a distinct and harmonious pronunciation.

It must, however, be considered at the same time, that the obtaining of this degree of utility by art, is not to be acquired without skill; indeed, the insertion of artificial teeth can be properly performed only by means of a comprehensive knowledge of the anatomy and physiology of the teeth, and all the parts connected with them, as well as a minute acquaintance with all their diseases.

The manufacturing of artificial teeth, therefore, cannot be left with safety to the artizan alone, however great his mechanical skill may be, like that of an artificial leg or arm, or even of the eyes, &c. yet this idea is as commonly received at present as it is erroneous and absurd.

So great, indeed, did I find the difficulty of obtaining any useful assistance from the mechanical dentist in America, that, during the whole of my

practice in that country, I was compelled to attend to this laborious branch of the art myself, as well as to the surgical treatment; and, I believe, it is principally in London and Paris, and a few other large European capitals, that the scientific dentist may receive some useful assistance from the mechanic.

Still, even with such assistance, the conscientious dentist will be compelled to add much time and labour to that of the best mechanic, if it be his determination to insert such artificial teeth only as are sufficiently *useful*, as well as permanently *harmless*, to the remaining teeth, and other parts with which they are connected.

Dental surgery, as a branch of the healing art, is yet a very obscure science, and, at all events, not less intricate than any other of its branches. It is of all others the least understood by medical men, as well as by the public at large, and hence the backwardness in drawing a just distinction between the mechanical and the scientific dentist, although there is in reality as great a difference between them as there is between the unpretending surgical instrument-maker who manufactures the artificial limb, and the surgeon whose duty it has been to amputate it.

If the facts just stated are duly considered, we can no longer be surprised at the frequent occurrence of individuals, even of the most exalted station, so much mistaken as to apply to the mechanical dentist for the insertion of artificial teeth, at a period when the various diseases of their mouths require surgical treatment. This sufficiently accounts for the frequent loss of all the natural teeth, after the insertion of a few artificial ones.

The following case is at once a very complete illustration of the pernicious consequences resulting from the injudicious employment of artificial teeth, and of their excellent effects when applied with judgment.

Mr. —, of —, requested my professional assistance in the year 1820; his age was about 55, his constitution delicate, and suffering greatly from an injudicious treatment of his teeth, which he had received at various periods. According to the patient's own account, in consequence of the insertion of a few artificial teeth at an early period of life, and a constant neglect of his own, he had successively found himself compelled

Irish apothecaries held in that city recently are ludicrous in the extreme: it would require the pencil of a Hogarth to do them justice. We could hardly believe that we were reading of the transactions of a sober body of men, met together for the protection of their rights, and for the serious purpose of reform. The whole proceeding rather reminded us of a "barring out" at school in the Christmas holidays. When we found, indeed, that there was to be a dinner at the upshot of the business, we had no objection, sensible as we are that all "enterprizes of great pith and moment" at the present day invariably end in that way. Considering, however, how serious an aspect things wore at one stage, we cannot but express our admiration at the happy issue to which they have been so cleverly brought—no matter by what means. What seemed likely to come to blows came only to a banquet; their "stern alarms were changed to merry meetings;" and our grave friends eventually drowned all their animosities in a bowl of punch.

It was a sort of aggregate meeting of the "art and mystery" which assembled in the Irish metropolis, and reform was the order of the day. For a considerable period, it seems, the corporate body, styled the Governor and Company of the Apothecaries' Hall, (established in 1791) has failed to give general satisfaction to the apothecaries of Ireland. Yet, if one might form an opinion from the opposite and apparently counterbalancing charges brought against the Hall, there would seem to be a possibility of its not being totally in the wrong. One party complains that the company (with whom rests the power of examining and of conferring licenses) bestow their honors too lavishly, and admit unqualified persons into the profession for the lucre of a paltry consideration; whilst another as loudly exclaims against the narrow monopoly of the Hall, and would be sa-

tisfied with nothing short of its utter abolition. All parties, however, seemed to agree that abuses did exist, and imperatively demanded redress. In this state of things the dissentients were fortunate enough to find a leader in Mr. Donovan, one of the most able chemists in the kingdom; and, as it happens, actually the governor of the company for the present year. Under his auspices it was hoped that an adjustment of the disputed points might be amicably effected, without prejudice to the interests of the corporation; and we believe we may congratulate the parties on the likelihood of an object so desirable being about to result from the labours of the newly-appointed committee. The transactions of the meeting, or rather of the series of meetings, of which we have given a rude outline, are too curious to be passed over so slightly; we must find room for a few particulars.

The aggregate meeting of the Licentiate Apothecaries of Ireland was held in the Apothecaries' Hall, Dublin, on Thursday, October 1st,—the Governor, Mr. Donovan, in the chair.

The chairman, in his opening address, dwelt on the necessity of the due observance of decorum. It was most probable they should be able to obtain a new legislative enactment to govern their body; and it was for the common interest, that whatever enactment should pass, the legislature should be such as would make their profession as high in public estimation as it ought to be. With such an object the present meeting had been convened, and he thought they were competent to entertain any question they pleased. He hoped no virulent observations would be introduced, or any topic brought into discussion which would tend to fritter away their time unnecessarily.

Several gentlemen requested to know what measures the Directors meant to adopt; upon which Mr. Madan, their

labarre. Of these, the last has, I believe, treated more extensively on the subject than any other dental writer. His "*Traité de la Partie Mécanique de l'Art du Chirurgien Dentiste*," in two volumes, accompanied with forty-two plates, is exclusively devoted to the mechanical part of dentistry.

But, although Dr. Delabarre is very deserving of the gratitude of the manufacturers of artificial teeth, for the great patience and research, by which he has endeavoured to facilitate their labours, still he has, like all other authors who have preceded him, dwelt very little on the surgical principles under which the different artificial preparations should be adopted; although it cannot be denied that the merits and demerits of all the methods of inserting artificial teeth which he describes, and with other authors recommends, must be entirely dependent on the principles under which they are applied.

Having, in the preceding pages, stated very generally the great advantages to be derived from artificial teeth, when applied with skill, as well as their injurious consequences if inserted without the necessary judgment, I now beg to make a few more particular remarks on those modes and malpractices which ought to be rejected, and to state, at the same time, the principles by which I have been guided in the mechanical part of my practice.

During the greater part of my residence in America I was obliged to unite the entire duty of the mechanical part of my profession with that of the surgical treatment of all the diseases of the mouth; and in a country which, above all others, offers the best school for the practical surgeon dentist. I have, therefore, both from necessity and opportunity, bestowed much attention upon this branch, more especially in all its bearings with curative and preventive treatment. I hope that, in laying before the profession the principles which I have adopted in my own practice for many years, I may not be altogether unsuccessful in rendering myself useful to my brethren.

In forming proper rules for this mechanical part of surgery, it will therefore be best, for the sake of distinction, to take into particular consideration, first, such treatment and practice as is injurious, as well as such as is proper and necessary; secondly, all those circumstances

which are either indicative or contra-indicative of the use of artificial teeth; and, thirdly, such modes of manufacturing and inserting artificial teeth as must be considered either positively or negatively bad, as well as those which are most useful and effective.

Of the Treatment of the Mouth previous to the Insertion of Artificial Teeth.

It must be perfectly evident to every surgeon, that, in a diseased state of the mouth, or its individual parts, as the jaws, sockets, periosteum, gums, or the remaining teeth, the unavoidable bearing of the artificial apparatus cannot be supported without great loss of health, and even gradual destruction of those parts to which the artificial teeth are affixed.

Whether the morbid state of these structures be founded on natural causes only or on the omission of surgical treatment, or whether it be partly aggravated and produced by injudicious treatment, matters very little in point of fact, although the degree of disease must greatly differ, and be much more extensive and complicated, under the latter than under the former circumstances. I have more minutely pointed out those modes of surgical treatment which I deem improper, in my "*Principles of Dental Surgery*;" and I have only to add, therefore, that, in every instance, by the application of artificial teeth, the pernicious effects of such modes are considerably aggravated; and that, under such injudicious treatment, the artificial teeth are rendered an additional exciting cause of all the diseases already affecting the mouth. Such, however, is the propensity of the public to take an erroneous view of the subject, that it generally requires the greatest persuasion to dispose the patient to submit to a proper and permanently useful treatment, while almost invariably he wishes, and not unfrequently persists, in desiring the adoption of such mal-treatment. Should the dentist yield to his request, the patient has one or two artificial teeth inserted, and, from refusing to submit to the treatment indicated by the state of his mouth, his teeth are gradually destroyed, until a whole artificial set becomes requisite, as in Case, No. 1. The injurious results of this practice are perfectly apparent, not only to the

surgeon, but to any one of common sense, by the following considerations. There is, perhaps, not one case in a hundred requiring artificial teeth, in which the other teeth are not more or less diseased, and the gums and alveoli also either primarily or secondarily affected. The mechanical and chemical bearing of the artificial teeth upon such diseased structures, naturally becomes a very powerful aggravating cause of the disease, even if they are well contrived and inserted; if, however, they are not well constructed, and are inserted with undue means or force, or held by too great or irregular pressure, or by ligatures, or other pernicious means for their attachment, the morbid effect is still more aggravated, and a general state of inflammation in the gums and sockets, and particularly in the periosteum, very rapidly follows. The patient, moreover, finds it impossible to preserve the cleanliness of his mouth; and his natural teeth, as well as the artificial apparatus, in combination with the diseases of the other structures, become a source of pain and trouble, and the whole mouth is rendered highly offensive and disgusting to the patient himself as well as to others. Indeed, that such is the fact I may confidently appeal to almost every individual who is now wearing a considerable number or a whole set of artificial teeth.

Thus, by the improper insertion of artificial teeth, the patient not only loses all the good effects of this treatment, but also his own remaining teeth, exposing himself for a considerable period to all the consequent diseases of the mouth, as well as of the constitution; whereas, by a proper treatment, the whole mouth would have been rendered and preserved perfectly healthy, the further loss of teeth would have been almost completely prevented, and the defect so restored as to prevent the necessity of increasing the number of artificial teeth for many years, or perhaps during life.

The too early insertion of artificial teeth after the surgical treatment of the mouth is completed, is also a consideration of no small importance, though too often entirely neglected. Indeed, even after the most judicious treatment of the mouth has been instituted, artificial teeth may be rendered a source of irritation and injury, if applied before

nature has perfectly produced those changes which always follow the extraction of teeth by means of absorption in the sockets and gums; and producing immediate inflammation in the parts not yet perfectly recovered, and soon losing their adaptation to the form of the gums, they must become the cause of constant irritation. Convinced of the truth of the above statement, I have made it an invariable rule during my practice in the application of artificial preparations, to bestow every necessary surgical attention upon each individual part of the mouth which the case required, so as to render the jaws, the gums, sockets, periosteum, and every tooth perfectly free from disease.

[To be continued.]

PECULIAR CEREBRAL AFFECTION IN CHILDREN.

*To the Editor of the London Medical
Gazette.*

SIR,

If you should have a niche in an early number of the Medical Gazette, which you do not know how to fill up in a more profitable way, you may insert the following reply to your correspondent, W. H.*

And, first, let me remark, that if I have had any satisfaction in having published my remarks upon "An Affection of Infancy resembling Hydrancephalus, but arising from Exhaustion," it has chiefly been that it has led to my name having so frequently appeared upon the same page with that of Dr. Gooch. Your correspondent attempts to establish a difference of opinion between Dr. Gooch and myself, inasmuch as I have ascribed the effusion into the ventricles of the brain in cases of exhaustion to congestion of that organ, whilst Dr. Gooch attributes it to an empty state of the cerebral vessels; and he considers that this remark of Dr. Gooch is the most valuable part of the inquiry. He never seems to have suspected that the question may not be fully determined.

I would beg, therefore, just to refer this gentleman to Dr. Kellie's well-known paper, in the first volume of the

* See Medical Gazette, No. 98, p. 84.

Great attention was paid to the man, during the time he continued in the hospital, by his dresser (Mr. Workman), as well as by the surgeon. This the man acknowledged before he left the house. The case went on as fractured thighs usually do, with the exception of the swelling of the leg. At about the end of the seventh week, on Thursday, the 6th of July, Mr. Key had the splints removed, in order to ascertain the condition of the fractured bone: the bone was found on this day to have united in a good line, but the union did not appear to be sufficiently strong to bear the weight of the limb, and the patient was cautioned against using it with any degree of roughness. The long thigh-splint was ordered to be discontinued, and the limb to be laid upon pillows. On the Monday following (July 6th) Mr. Key, in the presence of about twenty pupils, raised the limb gently, and again made a careful examination of it, and re-stated his opinion that a week or two must elapse before he would gain any degree of power in it; once more warning the man that any undue effort of the limb would only retard his recovery. On the Wednesday following the dresser met Mr. Key, and requested him to see the man, as the bone appeared to be broken, and he was about to leave the hospital. Upon seeing the limb, Mr. K. said to him, "Grant, what have you been doing with your limb—how comes it broken again?" "Oh, Sir," he replied, "you broke it yourself on Monday when you examined it."—"Why did you not mention it when I was at your bedside: did you mention it afterwards to the dresser?" Answer, "No."—"To the sister, nurse, or any of the patients?" Answer, "No."—"It is all nonsense; you have been using your leg improperly, and are now laying the evil consequences to me; however, the limb must be replaced in the splints, and you must have three or four weeks more confinement."

In the afternoon of the same day, as Mr. K. was quitting the hospital, the porter put a note into his hand, the contents of which were to urge Mr. K. to be on his guard, as there was good reason to suspect certain individuals were endeavouring to make use of Grant's case as the means of exciting popular feeling against Mr. Key individually, and Guy's Hospital in general.

Mr. K. therefore, returned into the hospital square, where, finding two or three dressers and some pupils assembled, he requested them to accompany him to the bedside of the patient. Calling for pen, ink, and paper, he said, "Now, Grant, I come to investigate this matter to the bottom; I am determined to know the whole truth of this accident to your thigh." Mr. Key then repeated the questions about the manner in which the thigh was fractured a second time, and received the same answers. "Now," said Mr. K. "be upon your guard, and tell me all that has occurred since I left you on Monday morning, as I understand that some designing persons have been persuading you to charge me with having broken the bone, and you must be yourself well aware of its being wholly untrue. The examination having been publicly made in the presence of the pupils, the circumstance of the bone being broken could not have escaped being noticed. Is it likely, if the bone had been broken, that you should have taken no notice of it either to myself, to the dresser, the sister, the nurse, or to the patients? Now, in the first place, how is it that your limb is not supported with pillows as Mr. Workman, the dresser, left it—who has taken them away?" Answer, "I don't know, Sir."—"Mr. Workman, have you taken them away?" Mr. Workman replied in the negative.—"Has the nurse taken them away?" The nurse declared she had not. It was at length discovered that the patient had himself taken away the pillows from under his limb, and was at that moment lying upon them. The motive for this deception Mr. Key could not discover, but proceeded to interrogate him further. "Have you been using any improper violence with the limb since I left you on Monday morning?" Answer, "No, Sir; I have remained in the same position in which you left me exactly."—"You will take your oath that no one has disturbed your limb, and that you have strictly obeyed my injunctions of keeping quiet?" Answer, "Yes, Sir, I will."—The nurse, who was present at the latter part of this interrogation, immediately said, "Sir, it is all false; for on Monday evening, at his own request, I made his bed; and although I advised him to the contrary, he would get up and sit in a chair."—"So, then,"

said Mr. Key, "I am now coming at the truth: you have been out of bed, although I particularly enjoined you to be quiet, and have broken your own leg, and now lay it to me. However, I forgive you, if you will discover to me who has been instigating you to tell these falsehoods. Nurse," said Mr. Key, "did he complain to you of his limb being broken when he got out of bed—was his limb supported by any splints while he was sitting in the chair?" Answer, "No."—"Do you now confess that you have been out of bed?" Grant confessed that he had.

It was thus entirely by accident that Mr. Key became acquainted with an underhand attempt to persuade this man to give a false statement as to the nature of the accident, with a view of injuring the professional character of his attendant; and had the patient been allowed to leave the hospital without the above information as to his getting out of bed having been publicly drawn from him, the attempt would most likely have succeeded. Fortunately, however, not only was the design discovered, but, by a timely investigation, the attempt has been frustrated. We shall only add, that the individuals concerned are perfectly well known to us, and that we shall keep a watchful eye on their future proceedings.

VACCINATION FROM THE COW.

SOME cows, in Hyde-Park, were recently affected with an eruptive disease on the udder, supposed to be *cow-pock*. Two attempts were made to propagate the disease to the human subject, but in both instances the experiment proved inefficient. In one case, no apparent effect was produced, and in the other only a transient and incomplete papulation resulted, and which died away without running on to vesication. At the time we saw the disease in the cow, it had passed into the form of crusts, from beneath which oozed a certain quantity of purulent matter. The genuine vaccinia in the cow would appear to be a rare disease in this part of

England: several attempts, similar to the above, have been made here, with an equally unsatisfactory result.

DEATH OF M. PELLETAN.

PELLETAN, the pupil and successor of Desault, died at Paris on the 26th of September, in the 83d year of his age, having for some time laboured under a chronic affection of the urinary organs. M. Pelletan, for many years, was at the head of his profession, and enjoyed the principal practice of the French capital. He was a man of good, rather than of brilliant talents; but was much respected for his amiable disposition and honourable conduct. Latterly he was thrown a good deal into the shade, partly by the infirmities of his advanced age, and partly by the more aspiring qualities of M. Dupuytren, who succeeded him at the Hotel Dieu. Pelletan was much followed as a teacher, being possessed of considerable eloquence; and during thirty years his renown extended over Europe. Yet so completely has he been forgotten of late years, that we believe few in this country were aware that he yet lived.

QUERIES.

To the Editor of the London Medical Gazette.

SIR,

If any of your readers will be kind enough to explain the subject of the following queries, he will oblige,

Yours, &c.

R. G.

Sept. 28, 1829.

1. Seeing that the inferior oblique muscle of the orbit is supplied from the motor oculi, which is a nerve of voluntary motion, how is that muscle concerned, as seems to be the opinion of some that it is, in rolling the ball upwards when the eye-lids are closed, which is an involuntary motion?—(See a lecture by Mr. Bell in the first volume of the *Gazette*.)

2. What is the use of the superior oblique?

EXTRACTS FROM JOURNALS,

*Foreign and Domestic.*EXTRACTION OF CATARACT BY MEANS
OF AN INCISION THROUGH THE
UPPER PART OF THE CORNEA.

THIS method, according to Graefe, offers numerous advantages over those more usually adopted. The consequences of the wound are less severe, and the sight is more perfectly relieved, because the lower part of the cornea remains untouched, and preserves its natural clearness and convexity. In eighteen individuals operated upon by the superior section, seventeen recovered their vision; in one only the cornea on one side became opaque, and this in consequence of a gouty inflammation which frequently returned.—*Bulletin des Sciences Médicales.*

APPLICATION OF A CONCENTRATED
SOLUTION OF NITRATE OF SILVER
TO THE EYE.

This method has proved so useful in atonic and obstinate ophthalmia, with copious discharge, that M. Graefe thinks it his duty to direct the attention of practitioners to it. The method adopted is to insinuate a drop of the solution, with a hair pencil, between the eyelids.—*Ibid.*

In this country, the above method is by no means unknown.—E. G.

NEW METHOD OF REMEDYING RUPTURE
OF THE PERINEUM.

M. Dieffenbach, of Berlin, who has published a work on the various methods of supplying mutilated parts of the body, suggests the following in rupture of the perineum:—After having wiped the lips of the lacerated part, and arrested the bleeding, he passes a curved needle, armed with a very strong thread, through the middle of the wound, and brings together the two sides of the fissure; but, in order to prevent the wound from being opened by the elasticity of the skin, he makes use of a very simple and ingenious contrivance, namely, making an incision in the soft parts in the same direction as the laceration:

thus the lips of the new wound gape, the suture no longer suffers any dragging, and the consolidation takes place with perfect ease. M. Dieffenbach employs no bandage to retain the suture, which, owing to the lateral incisions, requires no support; neither does he use any plugs, or sponges—nor, in fact, any thing else except cold applications.—*La Clinique.*

EFFICACY OF THE POMEGRANATE IN
TAPE-WORM.

A man, aged 37, pale and thin, had passed during six years rings of the *tenia*, which came away to the extent of five or six daily, causing excessive itching of the anus at each time. On one occasion he spontaneously expelled ten feet and a half of the worm. The patient calculated that he had passed in all as much as 3000 portions of worms, besides the 10 feet above mentioned, and 12 more which were brought away by remedies. M. Delaporte, by whom the case is related, made him take two ounces of the decoction of pomegranate root, and at the end of an hour and three quarters the patient expelled at once, and almost without any griping pain, twelve feet of a *tenia*, furnished with the head. It is extraordinary, adds the Doctor, that a remedy so efficacious and simple should be so little used.—*Journal Général.*

LACHRYMAL CALCULUS.

A middle-aged woman experienced pain, during two years, on the left side of the nose, with frequent fits of sneezing, and other symptoms of catarrh. Afterwards, a dryness of the nostril came on, with swelling and complete obstruction on the left side of the nose. This was followed by the sensation of a moveable body in the nose, and, soon after, she passed a concretion of some size from the nostril. It was nine lines in length and five in breadth; its colour was a brownish grey, and its structure very compact. Being cut across with a saw, its centre was found to consist of a cherry-stone, round which, concentric layers of different colours were ranged—green, brown, and white: the patient was unable to call to mind any circumstance connected with the introduction of the foreign body into the nose.—*Bulletin des Sciences Médicales.*

EXTIRPATION OF THE RECTUM.

M. Lisfranc has, in two cases, removed three inches of the lower part of the rectum. The patients have done well. One was operated upon five, and the other two weeks ago.—*Archives Générales*.

HIGH OPERATION FOR THE STONE—
LARGE CALCULUS.

M. Lisfranc lately presented to the Royal Academy of Medicine a urinary calculus, weighing seven ounces, which he removed by the high operation. Of three patients on whom he has performed lithotomy by this method, two, in whom he introduced a catheter into the bladder by the urethra, died in consequence of the infiltration of urine by the wound; in the third, the canula of M. Amussat having been placed in the wound, the urine did not escape into the surrounding tissues, and the patient is in a fair way of recovery.—*Ibid*.

mentations of rose-water, and afterwards cold spirits and water, without avail. On the 6th of September she was admitted at La Charité. The ball of the eye was slightly tumified; the vessels of the conjunctiva injected; the cornea of the affected side more prominent than the other, and perceptibly softer; behind it was seen an effusion of blood, occupying the lower part of the anterior chamber, changing its place with the movements of the head, and rising to a level with the edge of the pupil. The head-ache and pricking continued but slightly. The pulse was natural, but there were night sweats.

As this patient exhibited, at the same time, signs of gastric disturbance, an emetic was ordered on the 7th; which was the only treatment adopted till the 10th, when an astringent wash was prescribed; but, as yet, the blood effused has not been re-absorbed.—*La Lancette*.

HOTEL DIEU.

*Restoration of a great portion of the
Cheek by Operation.*

A CHILD, nine years of age, was affected with gangrenous inflammation, which destroyed the soft parts constituting the lower half of the right cheek, and extending from the symphysis to the angle of the lower jaw. The breach of surface was $1\frac{1}{2}$ inch in diameter in every direction. It left but a few lines of the commissure of the lips, and anteriorly was blended with the opening of the mouth. Backwards, it terminated a third of an inch from the anterior border of the masseter; beneath, it nearly reached the basis of the jaw. In the centre of the opening was seen the tongue, which had formed preternatural adhesions by which its movements were impeded, and mastication and deglutition rendered difficult. Another inconvenience, still more formidable, was the constant escape of the saliva. M. Dupuytren tried, about two months ago, to destroy the adhesions of the tongue, but his efforts have been nearly unavailing, as it has always united itself again to the edges of the perforation. About the middle of August, he directed his attention to the removal of the gap by which the saliva escaped. His plan

HOSPITAL REPORTS.

LA CHARITÉ.

Apoplexy of the Eye.

APOPLEXIES have prodigiously increased since the time of Laennec: thus we have apoplexy of the lungs, of the liver, of the skin, &c.; and to these we are now, it seems, to add apoplexy of the eye. Louisa Martin, aged 45, ceased to menstruate during three months without inconvenience. She had suffered some injury of the eyes in early life, from small-pox, and had always had weak sight. To these symptoms had lately been added some appearance of incipient cataract, and within the last twenty days she had been affected with an acute and permanent pain on the right side of the head, with throbbing. Besides this, however, there was no change in the habitual state of her eyes till the night of the 28-9th of August, when she experienced a sharp pricking in the right eye, giving the sensation of a foreign body, which she endeavoured to get rid of by rubbing the part. In the morning she found that the sight of that eye was lost. She applied fo-

was to borrow a flap of skin from the neck, to twist it, and apply it to the opening, having first cut the edges, so as to afford a raw surface. M. Serres, a young surgeon, of Montpellier, who saw the patient, suggested a proceeding analogous to that adopted for hare-lip. To this M. Dupuytren objected that the cicatrix thus formed would be kept constantly on the stretch, and that this would cause irritation, if not disorganization. At the same time, he acknowledged the risk of the flap sloughing, and that, even if it united well, it would still be without the buccinator muscle.

On the 30th of August, M. Dupuytren performed the following operation. He traced a flap on the lateral and upper part of the neck, anterior to the sterno-mastoideus; and having cut the edges of the breach in the cheek, he dissected the flap with care, avoiding to wound the external jugular vein; then twisted it on its pedicle, and fixed it by five points of suture. The wound in the neck was immediately united by means of three needles: the operation was long and painful. One or two small arteries were tied, and the patient replaced in bed, without any dressings having been applied. The first night was passed without accident; the child had some hours sleep.

Sept. 2d.—Moderate fever. The flap is alive; some points of suppuration on its edges.

During the night of the 2-3d, some delirium. Inflammation more intense. The flap beginning to separate from the lower part, in consequence of the suture tearing through the lip, it was retained by straps. Next night, delirium more severe; the flap separated at another point, and the opening extending between the two presented a vertical separation about an inch long. The fever now ran high, and the suppuration became fetid. The posterior and upper part of the flap appeared to live, and to have contracted from adhesions. The external edge seemed to be dead. All the sutures were now removed, and the parts supported by means of straps.

5th.—The symptoms abated; some points of suppuration continue on the edge of the flap, but the success of the operation is secure, with the exception of the separation above-mentioned, which will admit of remedy by the common process for hare-lip.

22d.—The consolidation of the parts being complete, the edges of the aperture which remained were pared and brought together with four twisted sutures. After this the case went on well, and the only remaining evil is the adhesions of the tongue. These, M. Dupuytren means, if possible, to destroy.—*La Lancette*.

HOSPITAL SAINT ANTOINE.

Amputation of the Thigh—Torsion of the Arteries.

A GIRL, seventeen years of age, reduced by suffering, but of good constitution, had the extremity amputated for "white swelling" of the knee. The operation was performed Sept. 21st. The crural and a small artery were completely twisted three times on their axis; after which, the soft parts were immediately united by means of straps, compress, and bandage. On the 24th, no accident of any kind had occurred. M. Velpeau then dressed the stump; every thing was renewed except the straps; there had been the slightest imaginable exudation of sanguineous serum, and the process of union had commenced.—*La Lancette*.

This patient gradually sunk, and died Oct. 2, from circumstances quite unconnected with the *torsion* of the arteries, the only interesting point in the case. There had been no bleeding. The femoral artery was pervious throughout, and there was no trace of inflammation. It is not mentioned whether there was any appearance of a plug.

ST. BARTHOLOMEW'S HOSPITAL.*

Wound of the Lung.

IN the course of last week a patient was admitted into the hospital with a wound of the lungs. He was a butcher, and when employed in killing sheep, the knife, by some accident, was thrown against the upper part of his chest. On the right side there appeared a puncture; the wound was half an inch in length. He was brought to the hospital soon after, and it was found that emphysema, in a moderate degree, had taken place in the neighbourhood of the wound; and that there was an extravasation

* Observations lately made by Mr. Lawrence, at the conclusion of one of his lectures.

of blood, manifested by its expectoration. These were two circumstances which, viewed in combination, shewed that the lung had suffered direct injury. In this case the breathing was not much disturbed—there was a little irregularity in it, not such as to indicate that any serious difficulty existed, but only such kind of disturbance as might naturally be supposed to arise from the circumstances. The treatment in this case consisted of free bleeding, about fifty ounces of blood being abstracted on the day of his admission; he was freely purged, placed in bed, and kept quiet. These means completely removed all the symptoms connected with inflammation, and the patient has gone on from that time without a single unpleasant occurrence. He is now in the ward, and apparently quite well; at least there has been no unfavourable symptom since the accident (about four days ago), that would lead us to suppose that a serious wound had been inflicted on the lung. It is a proof that the injury of a part, involving considerable danger, will, in some cases, go on well.

Question of immediate Amputation in Cases of severe Injury.

There is a patient in Darker's ward who has undergone amputation of the leg below the knee: there was also another patient who lately left the hospital that had the thigh amputated. I mention these cases because they tend to throw light on a point of great importance. In many instances of serious injuries, such as fractures, gun-shot wounds, and, in fact, in all cases where it is apparent that the part will require to be removed, it becomes a question whether this ought to be done *immediately*, or the operation be *delayed*, and if so, how long delayed? My opinion is, that in all such cases you should operate immediately. Though I say immediately, it sometimes happens that certain nervous symptoms, such as great faintness, coldness, and alarm, are produced by serious accidents, and in this state of depression of the vital powers, the performance of the operation is not advisable; therefore, by immediately, I should say within ten hours after the reception of the injury. In both the cases alluded to, the result of the operation has been favourable. In the woman, who was about fifty years of age, and had been knocked down by a carriage, the wheel of which passed over her leg, and dreadfully fractured the bones, the operation was performed under very disadvantageous circumstances. She came to the hospital very drunk—I performed the operation in the middle of the night, and she was so intoxicated that the limb was taken off without her knowing it; indeed, until it was removed, she was not aware that the operation was performed! I mention this

to shew, that she could not be deemed in a favourable state for the operation; recovery, however, took place without any unfavourable symptoms. When the stump was nearly well, there was a great deal of pain and heat, and this is not uncommon. These symptoms were removed by free bleeding and the application of leeches, and she recovered remarkably well. The other patient was a strong hearty man, accustomed to hard work. Amputation was rendered necessary by a violent injury in the foot, which was entangled in some machinery, and dreadfully smashed. The amputation, as I before said, was below the knee, and he lost a considerable quantity of blood during the operation, which arose from the fulness of the blood-vessels. Next day, there was some fever, his skin dry, pulse full, tongue white, and it was found necessary to bleed him from the arm. When the stump was opened the day after the operation, it looked by no means well; in fact, in a short time it assumed a sloughy aspect; no secretion of pus took place, but a thin serous kind of fluid proceeded from it: a partial sloughing of the integument, to the extent of about an inch, took place; this was accompanied by inflammation, and the parts adjoining exhibited so much of vascular action, accompanied with dryness of tongue and other symptoms of a febrile character, that I had blood taken from the arm. This, with other remedies, relieved the local symptoms, but he then passed into a state in which I deemed it prudent to allow him a little wine and water, and he slowly recovered under the employment of these means. Though he lost so much blood, there has been some inflammatory disturbance about the stump, with pain and swelling of the glands in the groin, so that it was necessary to apply leeches. He is, however, now doing well. The general result of the operation in these two cases, agrees with others where I have operated immediately after serious injuries, and I have no hesitation in saying, that I think the practice of speedy operation is by far the best in all such occurrences.

GUY'S HOSPITAL.

Malformation of the Genitals—Hermaphroditism.

AN individual, exhibiting this unfortunate irregularity of structure was admitted into Charity ward, Sept. 30th, under the care of Dr. Bright. She was then suffering under a severe form of fever, which rendered her constantly delirious, and, in a few days, proved fatal.

On her admission*, and more especially

* Speaking of her as a patient, we adhere to the sex then assumed. She was admitted as Mary Cannon, æt. 55 or 60.

when, in order to apply a blister to her head, it was exposed and shaven, every one was struck with the coarse and masculine expression of her countenance: this and her somewhat square and muscular figure were all the observations relating to her sex that were made during life; but the post-mortem inspection disclosed the following appearances:—

A body analogous to the penis was observed immediately beneath the pubic arch; not free or pendant, but bound down towards the perineum: its length was about 2½ inches, and it terminated in a somewhat bulbous extremity, a little like the glans, but without the usual delicacy of cutaneous organization, without any perforation for the urethra, and without a prepuce. On each side of this body there was a considerable fulness of the integuments, at first view resembling the female labia, but in reality analogous to the male scrotum, as, like it, they contained each a small testis. This separation, into its two halves, of the scrotum depended on the penis being bound down in the median line, as previously described. The testes were in size like those of a boy 6 or 8 years old, and were connected with vasa deferentia, which were found pervious, and considerably enlarged towards their termination. The vesiculæ seminales were very small; the prostate gland also was remarkably small, and was covered on its sides by a pair of peculiar muscles passing from the rectum to the neck of the bladder. The urethra terminated in the perineum, about one inch from the end of the supposed penis, and half an inch further there was a blind opening, which fancy might call the rudiment of a vagina, but which was probably nothing more than an enlarged lacuna. The tunica vaginalis was continued some distance up the cord, but at the ring was quite closed. There was a very minute trace of cremaster muscle. The pelvic viscera had no female character whatever, and the formation of the pelvis itself approached to the male rather than to the female standard. The mammae were considerably developed, but would have been thought small for a healthy female. The lips and chin were clothed with a few scattered, irregular, curling hairs, not more than are often seen on aged females. The outline of the figure, in its muscular development, squareness, and largeness of limbs, &c. was decidedly more male than female. The cerebellum was natural in structure, and if it differed at all from the usual development, was rather small, but this was by no means distinct. No other peculiarities, either diseased or congenital, were observed in any part of the body.

It appears that in the former part of her life, this hybrid had assumed the dress and habits of a man; at one time working in a

brick-yard, at another period acting as a groom; then as a milkman; and afterwards she kept a green-grocer's shop. Her habits and manners were rude and bold, sometimes indicating a degree of derangement; more than once she engaged with success in pugilistic encounters; and, it is said, manifested still less equivocally male propensities. For the last 7 or 8 years she has appeared as a female, calling herself Mary Cannon; and, it is odd enough, that she first sustained her new sex at a public-house, called "The World turned upside down," where she engaged herself as "maid of all work." She was not, however, fully received by her female fellow-servants as one of them; suspicion hung about her, and care was always taken to provide for her a separate bed.—M.

WESTMINSTER HOSPITAL.

Noli me Tangere.

JANE JENKINS, æt. 44, admitted July 1, 1829, under Mr. Lynn. This was a case of *noli me tangere*, remarkable for its having been finally cured by an attack of erysipelas.

About a twelvemonth before her admission, she had a pimple on her nostril, which she scratched off; this she continued doing repeatedly, until it had spread over the whole of her nose, upper lip, and part of the cheeks. There is a deep red or claret-colour extending an inch beyond the scabs on every side. She has, during the twelvemonth, had medical treatment, consisting of ointments, lotions, &c. but without much benefit. She is a washer-woman, and says she has lived regularly; she is married, and has had twelve children; she is evidently of irritable temperament, and states that her mind is uneasy, and that she frets a good deal. Complains of great pain in her head and face. She is a fat middle-sized woman; continues menstruating, and at these periods says her face is always much worse. Bowels rather confined; tongue pale.

27th.—She has been dismissed to-day in good health, and her face quite well.

Ruptured Liver.

William Spring, æt. 11, admitted Aug. 24, under Sir A. Carlisle.

This patient was brought in last night, having been knocked over by a cart, one of the wheels of which passed over his chest across the false ribs. He complained of great pain there. A dose of house medicine was administered. This morning he complains of some little pain "across the stomach," always lies on the right side, and is very drowsy.

Towards evening he complained of pain in the abdomen; the pulse was very small. At nine o'clock he died.

On examination, eighteen hours after death, the thoracic viscera were all perfectly natural, except, here and there, adjoining the pericardium and diaphragm, some little extravasation of blood. On opening the abdomen, nearly three pints of dark blood escaped, and it was found that the liver was ruptured completely across the right lobe, about an inch and a half in depth at the deepest part, and communicating with the vena cava. The intestines appeared natural, and shewed scarcely any trace of inflammation.

Operation for Entropium.

Mary Ann Hunt, æt. 26, admitted the 9th Sept. under Mr. Guthrie. Twenty years ago she had the measles, and subse-

quently a severe inflammation of the right eye, ever since which the eyelashes have been turned in. It is four years since the left eye was affected in the same manner, in consequence of an attack of inflammation.

On the 28th May, 1829, Mr. Guthrie operated upon both eyes, but in consequence of the inflammation that supervened, he was obliged for the time to give up his efforts to benefit her.

Sept. 30th Mr. Guthrie again operated on the right eye, making an incision at the outer and inner angle, dividing the cartilage to the extent of a quarter of an inch, and snipping a longitudinal piece of the skin out of the upper lid. The eyelid was then turned up, and secured in that position by three ligatures, one through each corner, and one in the centre, which were retained on the forehead by strips of plaister: a piece of simple dressing was placed over the eye, and a compress and bandage over each.

2d Oct.—There is a little discharge, but no inflammation, and she is going on well.

3d.—The inner ligature came away to-day, but the eyelid is well turned out, and she is in every respect going on well.

5th.—The middle ligature has separated to-day.

7th.—The other ligature was cut out, and the operation has completely succeeded, the eyelid being everted, and only a little stiffness remaining.

15th.—The left eye has improved considerably since the operation on the right.

GLASGOW EYE INFIRMARY.

Artificial Pupil by Incision.

ISABEL M'GREGOR, æt. 45. The lower third of right cornea presents a dense leucoma of a crescentic shape, which completely hides the pupil. The upper half of the iris is in close contact with the internal surface of the cornea, and its fibres are evidently on the stretch. (See fig. 1.) Discerns merely light and shadow with this eye. These symptoms are the consequence of an operation for extraction of cataract performed 15 months ago, which was followed by inflammation and protrusion of the iris.

In the left eye the pupil is of an oval shape, the long diameter running obliquely from above downwards. There is a small leucoma in the site of the incision of the cornea, made in extracting the lens from this eye; and some small shreds of capsule are seen within the pupil. The vision is tolerably good.

The patient being laid on her back, Mr. Mackenzie, sitting behind her head, made with the iris-knife a quarter section of the cornea, parallel to its edge at the upper and

temporal side. Fig. 2 shows the situation and extent, by a dotted line, of the incision of the cornea. (A) marks an opening made in the iris during the incision of the cornea. This opening was accidental, but served afterwards for introducing the short blade of the scissors behind the iris, while the blunt blade passed between the iris and the cornea. On account of the closeness of the iris to the cornea, the incision of the latter could not be completed without penetrating at one point (A, fig. 2) through the iris. Maunoir's scissors were now introduced, and the probe-pointed blade was insinuated between the iris and the cornea, the sharp-pointed blade passing through the opening already made in the iris; the blades were now brought together, and a transverse snip made through the fibres of the iris, for the length of about one-fifth of an inch. The artificial pupil thus formed immediately gaped widely. A considerable discharge of dissolved vitreous humor took place, both before and after the incision of the iris. Immediately after the operation she complained a good deal of pain and heat of the eye.

Fig. 1.

Fig. 2.

Fig. 3.

Si opus fuerit cap. haustum Anodyn. cum Tr. Opii gtt. xxx.

7th.—Eye watered much yesterday, but has ceased to do so to-day. Took the draught, and felt easier after it. Slept a little during the night. Two colocynth pills this morning.

8th.—No pain; pulse calm. A dose of calomel and jalap.

9th.—Rested ill in the night; skin rather hot; tongue red and chopped. No motion from the calomel and jalap. Had a dose of salts.

12th.—Continues tolerably easy, and opens the eye for a short time. Discerns light, but is as yet unable to fix it on any object.

13th.—Cap. ter indies Sulph. Quinæ gr. j.

19th.—Artificial pupil perfectly clear and open, of the size and shape represented in fig 3. Eye still too intolerant of light to permit her to fix it on objects.

24th.—With the assistance of a double convex lens, can see pretty distinctly. Intolerance of light much abated.

CONTRADICTION OF AN ASSERTION OF MR. HETT.

To the Editor of the London Medical Gazette.

SIR,

You will greatly oblige me by the insertion of this note in your journal.

In the number of the *Lancet* for Oct. 17th is contained a letter of Mr. Hett's, formerly a pupil of Guy's Hospital, in which he erroneously asserts the language of Mr. B. Cooper, at the anniversary dinner, to have been of so indelicate a nature as to induce a certain gentleman to leave the room. Now, sir, I, the son of the individual alluded to, take upon myself directly to contradict the assertion. That my father did leave the room is true, but from motives totally different from any which might tend to implicate the delicacy or character of Mr. Cooper as a gentleman, or lower him in the estimation of his pupils.

I do not wish to conceal my name or address. It is as follows:—

RENFORTH THOMAS SCARR, Jun.

20, Dean-Street, Southwark.

Oct. 17, Saturday Morning.

BOOKS RECEIVED FOR REVIEW.

Elements of General Anatomy. By R. D. Grainger.

A Letter to Lord Robert Seymour; with a Report of the Number of Lunatics and Idiots in England and Wales. By Sir Andrew Halliday.

Principles of Military Surgery. By John Hennen, M.D.

A Treatise on Neuralgic Diseases. By Thomas Prigden Teale.

A New Method of treating Burns and Scalds and certain Cutaneous Eruptions. By Michael Ward, M.D.

A Practical Treatise on Acute Abdominal and Pelvic Inflammation. By David Nich. Bates.

Strictures on the Economy of Health. By Z. W. Vincent.

Elements of Practical Midwifery; or, Companion to the Lying-in Room. By Charles Waller.

The Opening Address delivered at the Sheffield Medical Institution. By Arnold James Knight, M.D.

A Grammatical Introduction to the London Pharmacopœia and Preface; or, the Student's Self-Instructor. By S. F. Leach.

W. WILSON, Printer, 57, Skinner-Street, London.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

LECTURE V.

On Inflammation ;—its general Phenomena and Divisions.

In the last lecture, gentlemen, I alluded to the fact, that the vessels in an inflamed part, when examined after death, were found so much filled with blood as to make it appear that they were actually more numerous. Now, I should have entered rather more particularly on that occasion into a consideration of the appearances which inflamed parts generally exhibit after death. Under such circumstances, we find that all the textures are preternaturally red, and that the number of blood-vessels in the part seems to have increased, while they are all turgid with blood :—at the same time interstitial deposition is observed to have taken place in the structures generally.

When we come to examine the parts, they appear firmer than natural, notwithstanding which we find that they are more easily lacerated, and more readily give way under the application of any force, so that in point of fact the effect of the inflammatory process is to diminish the natural cohesion or firmness of the part affected ; and this is found to be the general result of the disease taken in its active period. This particular result is often seen in the brain, where a very peculiar softening takes place, described by the French under the name *ramollissement*—a softening which was originally observed without any reference to the cause which produced it. This result had been noticed by various pathologists, but they attributed to other causes that softening of the brain, which accurate examination has proved to be merely a change dependent on inflammation.

You will probably inquire what is the de-
100.—v.

position, which takes place in the texture of an inflamed part, that produces the firmness to the feel which we find after death. Now in answer to this it is generally stated, that the new substance thus deposited is *lymph*—*coagulated lymph*, or as it is sometimes called, *coagulable lymph*. It is stated to be nearly the same with the fibrin of the blood, that is, with the white tough part which we see when, by washing, we have removed the red particles from the clot or crassamentum. It is said to be completely analogous to the white buffy coat which is seen on the surface of the crassamentum, when the blood is drawn from a patient labouring under inflammation.

These observations do not extend to the swelling which is situated in the neighbourhood of the part I have mentioned—that is soft and not firm. The disease in such a part is not so violent as in the immediate seat of the inflammation itself. There it produces an effusion of serous fluid in the cellular texture, and is similar to what takes place in dropsy. We have an opportunity of seeing the nature of the substance effused under inflammation, by observing what happens when the serous membranes are affected, because there the substance which, in other parts is deposited interstitially in an organ, is effused upon the surface, and is, therefore, rendered more manifest to observation. When the peritoneum is inflamed, we find that there is a kind of glue, that is, a white semi-transparent substance, deposited upon it, by which the opposed surfaces which ordinarily are free and unconnected with each other, become in fact agglutinated. The word agglutinated is used, and is an appropriate expression, for the parts seem to be connected together by a white kind of glutinous substance.

This is the state which these membranes exhibit under slight degrees of inflammation ; but when the disease is more violent, you have an opaque substance, of a somewhat fibrous appearance, deposited in a con-

considerable quantity upon their surface, and in its chemical characters it corresponds very closely to the fibrin of the blood. This is the substance to which the name of lymph is given. In cases of inflamed serous membrane you see a large quantity of this deposited upon their smooth secreting surfaces: it is at first loosely connected with the parts on which it lies, and you can scrape it off with the finger, or the handle of a knife. But within a short period blood-vessels are formed in its substance, and these seem to be an extension of the blood-vessels belonging to the surface on which the lymph is effused;—at all events, we soon find that the substance, which at first is an inorganic deposit, becomes organized. This change takes place more quickly than you might have expected;—for instance, it has been found in an inflamed intestine that the blood-vessels have been formed in the lymph deposited on its surface within a very short period from the commencement of the inflammation. When the lymph becomes organized, it assumes, more or less, the nature of the part on which it is deposited. Thus, in cases of adhesion between the various organs contained in the cavity of the abdomen, the connecting parts are assimilated in their nature to the surface of the peritoneum; they constitute a smooth, polished medium of adhesion, preternaturally uniting the parts together, and presenting a surface which you cannot distinguish from the natural state of the healthy peritoneum.

[The lecturer here exhibited a preparation, consisting of an adhesion between the surface of the liver and the peritoneal lining of the abdomen, and pointed out that the new parts corresponded in their texture with that of the peritoneum.]

We can see the same phenomenon—that is, the deposition of lymph—in inflammation of the iris. We observe either that the lymph is deposited generally through the texture of the iris, altering its colour, and changing considerably the nature and appearance of its structure, or sometimes the lymph is deposited in a distinct mass, or patch, as if a glutinous substance had been deposited on the part. We find that the matter thus poured out constitutes the bond of adhesion. It is occasionally seen between the margin of the pupil and the capsule of the crystalline lens.

Now, in inflammation affecting the texture of a part like the hand, when the lymph is deposited in the interior, the phenomena are rather more obscure, and yet there can be no doubt, if we could see the nature of the process, we should find it to be essentially the same as that just detailed—namely, that, in the first instance, lymph is effused into the structure of the part; and secondly, that the lymph becomes orga-

nized; hence we find, from examination at a more remote period, that there is a preternatural thickness and consolidation of the textures. If there is a considerable deposition in the structure of the parts that should be free and loose, they become condensed, and preternaturally adherent to each other. Thus we can explain how, in cases of violent inflammation of a part like the hand, after certain symptoms have subsided, we find the consequent effects to be consolidation and stiffness of parts that should be soft and pliant. Sometimes so much hardness is produced by this interstitial deposition into the inflamed part and its subsequent organization, that it is said to take on the appearance of scirrhus; and, indeed, we find it stated in some surgical writings, and those, too, by individuals who have been regarded as high authority, that the production of scirrhus induration is one of the consequences of inflammation. Now this is quite an erroneous view of the subject: the product of a common inflammation is merely a simple induration of the tissues in which it is seated; and you can always distinguish, even in the worst form which parts may assume from this cause, the character of the natural structure. In cases of scirrhus, the organic changes proceed until the natural structure is lost and a new one is substituted in its place. The hardness that may succeed inflammation can only resemble scirrhus in that one single character, and in no other. Common inflammation never leads to such a production as that which we properly name scirrhus.

I enumerated to you, in my last lecture, the different effects produced by the inflammatory process, which are commonly called terminations of inflammation; and I pointed out the true nature of the process,—namely, that the inflammation does not terminate with the production of these effects, but goes on, often, indeed, little diminished in violence. I told you, that you were not to understand that each species of inflammation produced exactly one of these effects, and no more. On the contrary, you often have two or more of them combined together. In a case where there is considerable suppuration of the hand, you perhaps have a large portion of the integument mortified. There may be a combination of mortification and suppuration: you may have suppuration and mortification in one part, while the rest of the inflammation is speedily subdued—that is, got rid of by resolution; or with the formation of matter and mortification in one part, you may have a considerable swelling, from the interstitial deposition of lymph, in the surrounding textures. You are further to understand, that the inflammation does not necessarily come to an end after causing these effects: the pro-

gress of inflammation, and its effects, would be more simple, and much less injurious, if that were the case; but, after suppuration has taken place in one part of the hand, unless the case be judiciously treated, and the patient take good care of himself, suppuration will occur in the neighbourhood. Thus you find that inflammation, originally produced by a slight injury of one finger, will gradually affect the whole of the palm of the hand, and then proceed to the forearm, and produce extensive mischief. The view of inflammation which I have exhibited to you from the appearances it assumes in an external part, such as the hand, has been generalised—it has been made a kind of representation of what occurs in inflammation in the body at large. No doubt it is the appearances which inflammation exhibits in the external parts of the body, from their being immediately within our observation, that have given rise to the general notion we have of the nature of the inflammatory process. Now it may be observed, that the effects and nature of this process are the same, so far as we can trace them in the internal organs of the body; but our general idea of them certainly depends upon those characters which can only be satisfactorily ascertained when the disease is situated on the exterior. Hence inflammation of all parts has been said to consist in the combination of the four circumstances I have already detailed—viz. redness, swelling, heat, and pain. But I think, in order to make the enumeration of its characters complete, there should be two other circumstances added to these: we should take into view that important result, the interstitial deposition into the substance of the part; and we should also include in our view an event which is equally important—the impaired or suspended function of the affected organ.

We ought not to include in the general notion of inflammation the occurrence of those sympathetic effects which I mentioned in my last lecture, because they do not attend invariably. The sympathetic disturbances of the sanguiferous, the nervous, the digestive, and the secreting systems, which constitute, taken together, the phenomena of inflammatory fever, are only observed when inflammation is extensive, and at the same time is very violent, or affects an important organ. You have inflammation exhibiting all the circumstances that I have mentioned in some organs of little consequence, and producing hardly any sensible effect beyond the part itself. Sympathetic constitutional disturbance, then, is not a necessary character of inflammation; but when present, it is a very important practical point for you to attend to, because it denotes either a considerable degree of inflammation, or its existence in a part of consequence. It is further important, as often

leading you to a choice of means by which the inflammation is to be treated: for example, the existence of the sympathetic constitutional disturbance would probably determine you to use *general* rather than *local* bleeding.

The question, however, what is inflammation, is not satisfactorily answered by enumerating these circumstances. The redness, swelling, heat, and pain, are the *external* signs of the disease—they are the characteristics that denote its presence; but the question still recurs, what is the change in the state of the part that produces these four signs or symptoms—what is the alteration in the capillary system of a part that gives rise to redness, swelling, heat, and pain? Now I have already had occasion to mention that this is a point which hitherto has not been clearly made out. That this circumstance is not well understood you may readily suppose, when you find that the most opposite opinions are entertained even at the present period respecting the state of circulation in the inflamed part: some imagine that it is obstructed, while others, and I think with much stronger reason, hold that it is increased. I have alluded to the opinion which supposes it to be a condition of spasm; and one circumstance which has been particularly adduced in defence of this idea is, the suspension of secretion. When, for instance, inflammation is seated in a glandular organ, it has been said that the suspension of the secretion arises from a spasm in the minute vessels of the part. Now it does not appear to me to be necessary to recur to this explanation. The ordinary office of the capillary vessels of a gland is to perform a certain secretion; but in a state of inflammation, these capillary vessels are disturbed in their action—they are thrown into an unnatural state. That it can be no spasm in the vessels I think is clear, from the effusion of coagulated lymph into the interstices: unless the vessels were sufficiently pervious, this effusion could not take place; and the same circumstance is shewn by the fulness of the veins leading from an inflamed part.

Being unable to assign a name for the process of inflammation, and for the external change that occurs in the inflamed part, that shall precisely point out what it is that produces this phenomenon, we have been obliged here, as in other cases, to name the disease symptomatically, and describe it in the same way. Inflammation is derived from the term *inflammo*, and denotes heat to exist in the inflamed part. If we have been unable hitherto to depict the precise nature of the diseased affection in inflammation, which is of such common occurrence, which we see every day, and which constitutes so large a portion of all the diseases that we actually treat, you will not be surprised that

the various attempts which have been made to construct nosologies, grounded on a knowledge of the nature of diseases, should have altogether failed.

It is necessary that the four circumstances which I have already enumerated should be combined together, in order to characterize inflammation, because taking them separately, they do not prove the existence of it at all. Redness of a part occurs in blushing; it may be produced by mechanical friction; by rubbing any part of the body; yet here there is no inflammation. You may make a part of the body hotter than usual by exposing it to the fire, but you do not produce inflammation. Again, there is swelling in anasarca, and there is pain in a variety of complaints, and yet nothing like inflammation exists. In order to characterize inflammation, you must have these four circumstances combining together, and existing at the same time in a part, but they are not essential to proving the existence of inflammation, for it may be recognized without them. These circumstances prove that inflammation has reached a certain height; but slighter degrees of the same disturbance may exist in their absence. On the other hand, if there be a very violent degree of disturbance in the capillary vessels of a part, you will have swelling, redness, heat, and pain, but without any decided interstitial deposition, and the consequent changes which it produces, which changes afford the only criterion we deem sufficient to prove the existence of inflammation.

In the serous membranes we do not find that the texture of the part is swelled under inflammation; and I believe in many instances we shall hardly perceive it to be redder than natural. The arachnoid coat of the brain is frequently the seat of inflammation, but exhibits no redness. The texture of the membrane is thickened and rendered opaque, but not red. In the case of the iris we see the inflammation, and do not doubt its existence, although we cannot discover it to be swelled, red, hot, and painful. Indeed the situation and circumstances of the part hardly admit of these changes being exhibited. In the inflammation of the cornea we may see some distention of the vessels, though we cannot discern the four circumstances that I have mentioned as characteristic of inflammation in general. In fact, considering these characteristics as indicative of inflammation, they are only of importance in reference to the affections of external organs; for when we come to consider the state of internal parts, we cannot apply this criterion to them. We cannot tell whether the liver or the lungs be swelled, red, hot, and painful. How can we tell whether the retina of the eye be in that state? So that these four circumstances

are of general, but not of universal application.

Inflammation, gentlemen, is by no means one and the same process under all circumstances; on the contrary, it varies very greatly. If you cut or scratch the finger, inflammation will be produced; sometimes without any injury, inflammation takes place near the nail, constituting whitlow; the finger may be inflamed without the rest of the limb in an attack of erysipelas;—it may be the seat of the affection called chilblain; it may be affected also with gout or rheumatism. Here are six different states that may be exhibited in one and the same part: these states are all different from each other, and yet they are all called inflammation, so that you see under this general term a considerable variety of appearances is included.

The affection in the first place differs in degree; that is, there may be more or less of inflammatory disturbance: where there is more, the progress of the case is rapid; where there is less, it proceeds slowly. This distinction is denoted generally by the terms *acute* and *chronic*. Severity of symptoms and rapidity of progress are denoted by the term, acute inflammation; mildness of symptoms and slowness of progress by the term, chronic inflammation. Now, you are not to understand from this that there are exactly two, and only two, differences of degree, and constituting what are called acute and chronic. The words merely denote in a general way the difference,—in fact, there are numerous degrees, and you often are at a loss to determine to which division you should assign a particular inflammation. There are numerous shades of transition that connect the two together. The words acute and chronic are not, in point of fact, exactly opposed to each other: the epithet *acute* denotes the *violence* of the symptoms, while the term *chronic* denotes their *duration*. Now, in acute inflammation, it is this violence of the symptoms that particularly attracts notice; in the case of chronic inflammation, it is the duration, and the consequences of the disease;—so that the terms of acute and chronic are not precisely contrasted with each other as to their meaning. Acute inflammation is called also active, violent, or phlegmonous inflammation. The term, phlegmon, is frequently employed: it is derived from the Greek term, φλεγω, and is a name given by writers to inflammation when seated in the cellular membrane and skin—to the active variety of the disease, which terminates in abscess. This is a form of inflammation that has been selected as a type of the disturbance, being one in which the inflammatory characteristics are strongly marked. The examples which we have already given to illustrate the in-

flammatory process in the hand, will shew you what is the nature of acute—active—phlegmonous inflammation. It is a violent disturbance that cannot last long; unless it is cut short by proper treatment, it will soon produce either mortification or suppuration; it is too active an affection to endure for any length of time; like fire, it soon burns itself out. Chronic inflammation is called languid, slow, or indolent; its characteristics differ materially, in several important points, from those of the acute kind. The vascular distention and disturbance are not so considerable; the redness is much less—often hardly any is perceptible, and the pain is slight. Chronic inflammation may occasionally take place in a part, and proceed some time, before the patient is aware of its existence. But although, in these respects, chronic inflammation appears to be a less serious disturbance than acute, in another point of view it is of greater consequence: there is a more extensive interstitial deposition, and consequently a greater and more serious change of structure in the affected organ.

Now, with respect to the deposition which takes place in chronic inflammation, we really are not able to speak very clearly about it. It is difficult to know the precise nature of the new matter that is formed under these circumstances. But if we take the example of the testicle, which is often the seat of this kind of change, we shall find, on cutting into it, that there is a considerable quantity of new matter, quite different from the natural structure of the part. If the testicle thus diseased be injected, the new matter is distinguished by its only partially admitting the injection. [The lecturer illustrated this point by exhibiting a preparation.] In serous membranes also we frequently see new productions formed under chronic inflammation, and they are of a very marked kind; [presenting a preparation, the lecturer said] this is an example, in which a complete adventitious membrane has been formed on the inner surface of the dura mater and the upper surface of the pia mater, in consequence of chronic inflammation in the head.

Thus you see, in acute inflammation, there is a violent disturbance of the part, which is of a temporary kind—quickly passes by, and the part recovers its natural state. In chronic inflammation the appearances are less alarming; the disturbances seem less serious and momentous; but the change of structure that is produced is much more considerable, and the results of chronic inflammation very seriously impair, or even destroy, the functions of the affected part. The danger, then, of the two appears nearly in an inverse ratio. You would suppose, when you looked at phlegmonous inflammation, that it would produce

the most disastrous kind of disturbance in the part; but when you observe the change of structure which chronic inflammation is capable of producing, you find that it is a much more uncontrollable process, and is attended with much more formidable mischief. We frequently hear and read of the expressions—the acute and chronic stages of inflammation. If we survey any particular case of inflammation, we do not find that it is one and the same process throughout: we observe, in fact, that there is a succession of phenomena; we find that inflammation commences insensibly, gradually increasing, till it acquires a certain development. It remains for a time in that state, and then gradually recedes as the part recovers a healthy condition. The whole of the circumstances embraced in this course pass under the name of inflammation, and yet the various portions of its progress differ considerably from each other. If we were to divide each inflammation into three periods, a period of formation in which the symptoms arise and proceed to a certain extent, a period of full development and a period of decline, we should find that the two first of these are nearly alike in most cases of active inflammation—there is no great difference in respect of the length of time they occupy; but the third period, or the decline—that portion of time which intervenes from the point at which the symptoms begin to lessen until the part recovers its natural state, differs much in its duration in different instances. When the inflammation is very violent—when it is allowed to pursue its progress uncontrolled—and more particularly if the circumstances that have excited it still continue to act, although the more violent symptoms may become lessened after a time, yet the state of inflammation continues for a long period before the part recovers its natural condition. The part is still inflamed, but the pain is less; the interruption of function is not so great, and this minor degree of inflammation, which continues for a long period under the circumstances that I have mentioned, is called frequently the chronic stage of inflammation; the former period, in which the symptoms are more violent, being called the acute stage.

Thus the terms acute and chronic are employed to distinguish different periods of one and the same inflammation. If inflammation is actively treated—if judicious means are employed, which arrest the inflammation suddenly, the part recovers its natural state very quickly, and you can hardly say that any chronic stage occurs. Some persons have not only employed these terms to designate the progress of one and the same inflammation, but they have frequently contended that these two periods are totally different in their nature, and produce

a different disturbance. The acute stage is regarded as the result of the increased action in the part, and the chronic stage as the result of the weakness, or debility, of the part; and they have founded on this alleged difference a corresponding difference in point of treatment, for they have contended that the atonic state requires tonic and stimulant treatment.

I consider that this view is erroneous. Without undertaking to say that there is no difference between acute and chronic inflammation in general, I have no hesitation in affirming that such difference does not exist between the acute and chronic stages of one and the same inflammation. I admit that there is a difference of *degree*, and that the chronic is a period of less violent disturbance, but still it is the same *kind* of disturbance; and in proof of this, we find that the acute form may pass into the chronic, and the chronic may relapse into the acute. When inflammation of the eye has arrived at the chronic stage, if the person be imprudent, or from various other causes, he may have all the phenomena of acute inflammation reproduced; and when you find that within a short period one stage can pass into another, and *vice versa*, you cannot admit the notion that these two stages are opposite to each other in their nature, and in the treatment they require.

Again, sometimes we hear of *active* and *passive* inflammation, which is an expression that to me conveys no clear distinction, and I for one deem it erroneous. I mentioned to you generally the idea that inflammation was increased action, and consequently passive inflammation conveys a contradiction in terms. This notion of passive inflammation is founded on the same erroneous view that I have just mentioned respecting the chronic stage, namely, that there is a kind of inflammation depending on a debility of the part. Admitting that acute inflammation depends on augmented action, it has been contended that chronic must depend on the contrary. I know of no such state myself. It is true, inflammation will differ very much, particularly in respect of treatment, as it occurs in weak or strong subjects; but the difference of the general state of the subject in which inflammation occurs is another point, from a difference in the state of the part itself. What I mean to contend for is, that no inflammation derives its origin from a state of weakness in the part itself; and although the state of weakness in the constitution generally may be *remotely* a cause of many inflammations, yet when the disturbance occurs, it is from an increased action of the vessels of the part.

We also hear of the arteries and veins as being in a state of *congestion*, in speaking of the different conditions in which an inflamed part is found. I acknowledge

this conveys no correct idea to my mind. The minute vessels of a part—the capillary system, in which inflammation seems essentially to reside, is intermixed in its ultimate ramifications with the textures constituting the organ, so that we cannot distinguish one from the other. Our means of distinguishing this order of vessels do not go very far;—after we have got beyond a certain point, there is no distinction that we can make between arteries and veins, and, therefore, we are unable, in reference to the living state of a part, to see their precise condition.

Inflammation differs essentially in the effects it is capable of producing. When the causes of disease are applied to internal parts, we sometimes observe derangement in a function without our knowing exactly if there be a change in the condition of the part, and we call this state of disorder, *irritation*. This, probably, is the commencement of that disturbance which in a more advanced condition would be inflammation. We sometimes see that there is merely distention in the vessels of a part, which is called *congestion*; sometimes the state of the vessels is evinced by a discharge of blood;—*hæmorrhage* occurs, and this may take place either from a free surface, as of a mucous membrane, or it may take place in the interior or substance of an organ. Again, we have the effusion of serum, the effusion of lymph, the formation of pus—*ulceration*: these are the varieties in point of fact which characterize different degrees of inflammation. We have not, perhaps, any direct data for saying that the kind of disturbance in the part which we call irritation, or disorder, is *actually* the commencement of inflammation, we only say it is *probable*. In fact, the word irritation, if employed in contradistinction to inflammation, does not denote any definite state of a part that I am acquainted with. Generally speaking, the word *irritation* is rather used to denote those symptoms which arise from affections of the nervous system; but we also use it in another sense—for instance, we speak of the irritated state of the stomach or alimentary canal. I think we ought to be able, by an accurate analysis, to resolve those conditions in which the term irritation is applied into something like inflammation; but if it is used in all those states in which derangement of the nervous system is involved, we shall then find that irritation cannot well be distinguished from inflammation. Now the various effects I have just mentioned, in point of fact, are generally ascribed to a difference in the degree of inflammation—but not entirely so. *Hæmorrhage* is the result of increased action, which chiefly shews itself in the mucous membranes: hæmorrhage into the substance of a part is rather an uncommon occurrence; it takes place,

however, in the affections of some internal organs. I fancy an instance was hardly ever known of abscess forming in the spleen; and it is very rare to see it in the kidney. Abscess in the liver is uncommon in this climate, though it is not so in some others. Thus there are peculiarities in the effect produced by inflammation that are not altogether referable to a difference of degree.

Inflammation, then, differs very much in its nature; the difference being, in a great measure, referable to the cause that has produced the disease. I have already mentioned the difference between common and specific inflammation, which must be referred to this head, and I need not particularly advert to the point again. I will only observe, that in specific inflammation we generally find there is a tendency to some particular kind of change in each case: in syphilis, for instance, we find that inflammation generally terminates in ulceration; in scrofula, the formation of abscess, and the deposition of tubercles in various organs, are the most ordinary termination. In common cases, there is a general, regular, and uniform progress of inflammation, from the first commencement to the termination; in specific inflammation, however, there are frequent irregularities in its progress. Sometimes the phenomenon that I have already mentioned—the sudden disappearance (called by the French *delitescence*) is observed. It is by no means uncommon in gout and rheumatism to see inflammation suddenly stop in one part, and then as suddenly appear in another; and this particular occurrence has been called *metastasis*, which means transference of disease. The idea that has been entertained of metastasis is, that the diseased matter which was seated in one organ was transfused or removed to another. It is an explanation founded on the old ideas of the humeral pathology. Now without entering into any such mechanical view of the subject of metastasis, I may mention that it frequently happens in gouty and rheumatic diseases, that they depart from the part in which they are seated, and other distant parts become as suddenly affected. That is all we can detect in metastasis—we see the removal of the affection from one part, and its increase in another. An individual has a swelling on some external part of the body, and we have the swelling suddenly removed, and perhaps inflammation comes on in the lungs and heart; but how it happens, we cannot tell.

These are some of the material points in which inflammations differ from each other; there are some points of minor consequence, which it is only necessary to allude to generally. Inflammation differs according to the temperament of the individual in whom it occurs; it also differs according to the age,

the sex, and the mode of life. Inflammations are also influenced by the state of climate and atmosphere in which the individual lives; and hence we find, under particular circumstances, that certain kinds of inflammation will take place in a great number of persons; thus, more particularly in hospitals, you will have a great number of cases of erysipelas.

I shall proceed with the *Causes of Inflammation* at our next meeting.

DUPLEX BOYS.

To the Editor of the London Medical Gazette.

SIR,

YOUR publication of an interesting case of a living double child, related by Mr. Borland, in a late number, induces me to believe that a more detailed account of the joined Siamese children than has yet appeared in this country, may prove acceptable to your readers. The accompanying statement was drawn up by Dr. Warren, of Boston, and is addressed to a respectable gentleman in that city. It has been transmitted to a friend of mine in London, who has kindly furnished me with it. The public will, before long, have an opportunity of seeing these boys, as the gentlemen who have had them conveyed to America propose that they shall visit London and Paris.

I am, Sir,

Your obedient servant,

JOHN ASHBURNER.

5, Wimpole-Street,
18th Oct. 1829.

Dear Sir,—In compliance with your request, as well as in obedience to what I consider to be a professional duty, I undertake to give some account of the Siamese boys, and particularly of the medium by which they are united together.

The boys are supposed to be about 18 years old. They are of moderate stature, though not so tall as boys of that age in this country. They have the Chinese complexion and physiognomy. The forehead is more elevated and less broad than that of the Chinese, owing to malformation. They much resemble each other; yet not so much but that, upon a little observation, various points of dissimilarity may be noticed.

The substance by which they are connected is a mass two inches long at its upper edge, and about five at the lower. Its breadth from above downwards may be four inches; and its thickness in a horizontal direction two inches. Of course it is not a rounded cord, but thicker in the perpendicular than in the horizontal direction. At its lower edge is perceived a single umbilicus, through which passed a single umbilical cord, to nourish both children in the foetal state. Placing my hand on this substance, which I will denominate the cord, I was surprised to find it extremely hard. On further examination, this hardness was found to exist at the upper part of the cord only; and to be prolonged into the breast of each boy. Tracing it upwards, I found it to be constituted by a prolongation of the *ensiform cartilage of the sternum*, or extremity of the breast-bone. The breadth of this cartilage is an inch and a half; its thickness may be about the eighth of an inch. The cartilages proceeding from each sternum meet at an angle, and then seem to be connected by ligament, so as to form a joint. This joint has a motion upwards and downwards, and also a lateral motion; the latter operating in such way, that when the boys turn in either direction the edges of the cartilage are found to open and shut. The lower face of this cartilage is concave; and under it is felt a rounded cord, which may be the remains of the umbilical cord. Besides this there is nothing remarkable felt in the connecting substance. I could distinguish no pulsating vessel.

The whole of this cord is covered by the skin. It is remarkably strong, and has no great sensibility; for they allow themselves to be pulled by a rope fastened to it, without exhibiting uneasiness. On ship-board, one of them sometimes climbed on the capstan of the vessel, the other following as well as he could, without complaining.

When I first visited the boys, I expected to see them pull on this cord in different directions, as their attention was attracted by different objects. I soon perceived that this did not happen. The slightest impulse of one to move in any direction, is immediately followed by the other; so that they would appear to be influenced by the same wish. This harmony in their movements is not the result of a volition, excited at the

same moment. It is a habit, formed by necessity. At an early period of life, it is probable they sometimes differed. At present this is so rarely the case, that the gentlemen who brought them have noticed only a single instance. Having been accustomed to use the cold bath, one of them wished it when the weather was cool; to which the other objected. They were soon reconciled by the interference of the commander of the ship. They never hold a consultation as to their movements. In truth, I have never seen them speak to each other, although they converse constantly with a Siamese lad, who is their companion. They always face in one direction, standing nearly side by side; and are not able, without inconvenience, to face in the opposite direction; so that one is always at the right, the other at the left. Although not placed exactly in a parallel line, they are able to run and leap with surprising activity. On some occasions, a gentleman, in sport, pursued them round the ship, when they came suddenly to the hatchway, which had been inadvertently left open. The least check would have thrown them down the hatchway, and probably killed one or both: but they leapt over it without difficulty.

They are quite cheerful; appear intelligent; attending to whatever is presented to them, and readily acknowledging any civility. As a proof of their intelligence, it is stated that, in a few days, they learned to play at drafts well enough to become antagonists of those who had long been versed in the game.

The connexion between these boys might present an opportunity for some interesting observations in regard to physiology and pathology. There is, no doubt, a network of blood-vessels and some minute nerves passing from one to the other. How far these parts are capable of transmitting the action of medicines and of diseases, and especially of what particular medicines and what diseases, are points well worthy of investigation. Captain Coffin informed me they had never taken medicine since they had been under his care. Once they were ill from eating too heartily, but were relieved by the efforts of nature. He thinks that any indisposition of one extends to the other; that they are inclined to sleep at the same time, eat about the same quan-

tity, and perform other acts with great similarity. Both he and Mr. Hunter, the gentleman who united with him in bringing them here, are of opinion that touching one of them when they are asleep, awakens both.

The pulsations of the heart are exactly alike in both boys. I counted seventy-three pulsations in a minute, while they were sitting; counting first in one boy, then in the other. I then placed my fingers on an arm of each boy, and found the pulsations take place exactly together. One of them stooping suddenly to look at my watch, his pulse became much quicker than that of the other; but after he had returned to his former posture, in about a quarter of a minute, his pulse was precisely like that of the other boy. This happened repeatedly. Their respirations are, of consequence, simultaneous.

This harmony of action in primary functions shews a reciprocal influence, which may lead to curious observations and important deductions. Whether it will be in my power to obtain any further information in regard to them, is uncertain. If not, some one else can better accomplish the task.

Let me add, that there is nothing unpleasant in the aspect of these boys. On the contrary, they must be viewed as presenting one of the most interesting objects of natural history which have ever been known to scientific men.

You are at liberty to employ the above statement in such way as you think likely to be useful.

I have the honour to be, yours, &c.

JOHN C. WARREN.

[There can be no doubt, as it appears to us, but that these individuals might be separated by a very simple operation, and almost with the certainty of giving to each the advantage of a separate existence.—E. G.]

MODE OF SWALLOWING POISON WITH IMPUNITY.

To the Editor of the London Medical Gazette.

SIR,

I BELIEVE no one has suggested any plan by which a person could swallow arsenic and Prussic acid without their producing any ill effects, in the manner

which M. Chabert is reported to have done. That M. Chabert may have discovered an effectual antidote to one poison is possible; but that he should discover antidotes to poisons of all descriptions, as he represents, is not to be credited. I believe that in the following mode a dexterous man might swallow poison without being injured by it.

Let an elastic gum tube be procured, as long as the œsophagus, and as broad as it will admit, without impeding respiration by its pressure upon the trachea. To the end of this attach a pig's bladder, and pass the bladder into the stomach with the tube attached to it. The upper part of the tube will of course occupy the upper part of the pharynx, and it may be fixed in its situation by two thin pieces of silk, or silver wire, attached to it, and carefully wound round the last dens molaris. As the œsophagus, when undistended, lies in a collapsed state, it will be understood that it will leave no space between the tube and its inner membrane, particularly if the tube is a little expanded at its upper extremity, corresponding to the shape of the pharynx. When a person attempts to swallow with the tube fixed in this situation, the pharynx will contract closely upon it, and prevent any portion of the substance swallowed from passing between the sides of the instrument and its inner membrane. The substance swallowed will of course find its way into the receptacle provided for it within his stomach by its own gravity. There have been instances of people who contrived to pass knives a considerable distance down the œsophagus; and if this be practicable, surely a bladder might be passed with a tube attached to it. I am much astonished that no one has suspected M. Chabert of swallowing poison in this manner. It appears evident that the poison passes down his œsophagus; but whether it passes through a tube contained within it into the bladder or stomach of some animal, or immediately into his own stomach, I leave your readers to judge. Perhaps this communication may induce some gentleman to pass a probang (if M. Chabert will allow him) with a view of endeavouring to discover it.—I am, Sir,

Your humble servant,

R. S. RICHARDSON,

Bedford-Place, Oct. 20th, 1829.

DETAILED NOTES

OF

BARON HEURTELOUP'S FIRST PUBLIC OPERATION OF LITHOTRITY.

From the Manuscript of his Work.

(Communicated by Mr. RUTHERFORD ALCOCK.)

The Patient 30 years of age—voluminous stone—Catarrh of the bladder—the Evidur instrument employed to seize and break the stone, the three-branch instrument used to extract the fragments—complete cure of the patient—no fever either during or between the “seances” for the operation.

JEAN JOUVEAUX, native of Villebout, department of Loir and Cher, of good constitution and 30 years of age, of bilious and sanguineous temperament, day labourer, experienced, in 1821, all the symptoms which denote stone in the bladder; a small calculus passed by the urethra a year after the first symptoms were observed. He suffered for five years, and determined on the 6th of Sept. 1826, on entering the Hotel Dieu.

Baron Dupuytren, chief surgeon of the Hotel Dieu, confided this patient to my care, that I might *publicly* perform the operation of lithotrity.

On performing a “methodical catheterism*,” I found the bladder about three inches wide, not very large from before backwards, and deep under the neck. The existence of a stone of considerable size was ascertained, moveable, rolling; and the bladder, notwithstanding rather a severe catarrh, was only of moderate sensibility. The urine was loaded with a slimy yellow mucus, adherent to the bottom of the *pot de chambre*, and in sufficient quantity to form a sediment in a large vessel, where the urine was deposited, the depth of a finger.

Notwithstanding this catarrh, I decided on operating, judging that it was rather a symptom of the existence of a stone, than the result of a serious disease of the bladder. The easy distention of this organ assured me that the

whole substance of the bladder did not participate in the disease, and that the mucous membrane alone was affected.

I decided then upon performing the operation, and on account of the size of the calculus, I began first with my instruments for excavating it.

The patient being placed on my operating bed, in a convenient posture, with the feet in the sandals, an injection of water was first made, to dilate the bladder; the organ being distended, the “pince à forceps” was introduced, opened, and drawn gently towards the neck of the bladder; the “pince servante*,” introduced within the “pince à forceps,” enabled me to ascertain that the stone was beyond the open branches of the “pince à forceps;” I therefore seized it with the “pince servante,” and drew it within the branches of the former. In this manner the stone was fixed without any movement of the instrument, and firmly seized and retained by the four branches of the “pince à forceps,” and then submitted to the action of that part of the instrument destined for its destruction†.

The forceps retaining the stone, and being fixed by the vice attached to the bed on which I operate, I now made a hole in the stone, two-thirds of its thickness, with the perforator. On removing the perforator, the evidur was introduced, and I excavated the stone until the walls fell in fragments with a slight noise.

Injections of warm water brought out immediately a considerable quantity of thick white pulpy matter, which coming out from the cavity of the stone

* The “pince servante” forms a part of the “evidur à forceps,” and is a delicate three-branch instrument within the principal, or mistress forceps, as Baron Heurteloup sometimes calls them; and, introduced through the cylinder, seizes the stone, and places it conveniently within the larger branches.—J. R. A.

† The four branches of the “pince à forceps” are moveable separately, so that they may each, one after the other, be drawn down firmly upon the stone, which, supported at four points, can no longer move, and is thus adapted in the best possible manner to be acted upon by the excavating instrument, which acts within the branches, and of course within the stone. The branches of the “perce pierre” of MM. Leroy and Civiale, being all attached to the same tube, and dependent upon each other, cannot very perfectly grasp a large stone; for the curved points which form the extremities of these branches do not all three press equally upon the stone, and, consequently, cannot hold it sufficiently firm to resist the action of the evidur. It may frequently hold a stone well enough to allow a perforation to be made with a simple drill head; but even with this it is often liable to slip.—J. R. A.

* It has been already explained in a former number (present vol. p. 1) in what Baron Heurteloup’s “methodical catheterism” consists.—J. R. A.

in flakes, gives evident proof in favour of the system I have adopted for the destruction of foreign bodies in the bladder: for to effect this, I only required to seize the stone *once*, and submit it *once* to the action of the instruments destined to break it up. The patient also was perfectly free from pain, and during the action of the instrument publicly expressed this, saying he was so easy that he could almost go to sleep*.

Immediately after the first attack, Jean Jouveaux felt relieved, and no longer experienced those painful sensations produced by the stone while entire. Its walls now broken, and its centre excavated, presented no longer a compact body, striking the neck of the bladder in walking. Lighter, and less liable to roll, these fragments ceased to give pain to the patient. Hence this first sitting was followed by great relief, and he felt better than he had been for a long time. No fever supervened, and the urine was charged, during some days, with a considerable quantity of powder and small fragments, which were observed to be immersed in the catarrhal matter, which, during the first two days, was as abundant as before; after that it gradually diminished until the sixth day, when I thought it advisable to relieve the patient of the shell fragments which still remained in the bladder.

The patient placed in the same position as in the first sitting, the bladder was injected, and the three-branch instrument, "a foret simple†," was introduced with ease, and several fragments were submitted to its action, either by the rotatory motion of the

drill effected by the how, or by pressing the head against the three branches. In this sitting the instrument was opened five times, and a fragment seized each time the branches were closed. Powder and fragments were immediately voided by the patient, and he continued doing so in the three following days. The catarrh evidently diminished.

In six other sittings, some of the remaining fragments were reduced to powder and very small morsels, and, after each time, the catarrh progressively improved: first as to its quantity, and afterwards in quality; for, from the discharge being mucous and purulent, it became simply mucous. There was nothing remarkable in these last sittings, except that the patient had a little difficulty in ejecting some of the fragments, but they were easily drawn forward to the meatus urinarius by properly adapted forceps, and there broken without any pain. No febrile symptoms occurred, to indicate any irritation of the organ, during the whole of his treatment. The patient had a quarter of his usual diet taken off, and was allowed to walk about the hospital. He was ordered a warm bath a few times after the application of the instruments, and recommended to drink freely of barley-water, to facilitate the expulsion of the fragments.

At the end of September he was sounded by Baron Dupuytren, M. Breschet, and M. Sanson, surgeons to the Hotel Dieu, and no vestige of stone was found. The patient left the hospital, anxious to join his family, and without allowing me to introduce the instrument, in order to be completely convinced of his perfect cure.

Some time after, I saw this patient, and having questioned him as to the state of his health, I learned that the jet of urine was not uniform, and, though he suffered no pain in voiding it, I thought it desirable to introduce an instrument. After some search, I found a fragment of a few lines in diameter, which was seized, broken, and ejected immediately. A second exploration with the instrument convinced me of the complete cure of the patient.

Reflections—It is now three years since Jean Jouveaux was relieved of his stone, and his health has continued good ever since; no symptom or sensation has been experienced, to throw any doubt on the completeness of

* I only mention this circumstance of the patient having thus publicly expressed his perfect tranquillity during the excavation of the stone, because his expression proves more than any argument how little pain it causes. It may, however, be easily conceived that in some patients no painful sensation should be experienced, since, during the operation, the instrument is immovable; the action of the mandrin is effected within the forceps, which retains the stone; it is destroyed from within outwards; and, consequently, the whole action takes place, until it is broken up in fragments, within the stone; and, finally, the whole takes place in the water with which the bladder is full, and in the middle of which that part of the instrument retaining the stone is of course placed. Every part of the canal and bladder being thus protected, the patient ought to have no pain, except what may arise from the presence of a sound in the bladder, and this in some patients, as experience daily proves, causes scarcely any painful sensation.—J. R. A.

† M. Heurteoup had not at that time his "brise coque," which would have terminated the operation much more rapidly.—J. R. A.

his cure. This operation was publicly performed, before Baron Dupuytren, Professor Breschet, and Dr. Sanson, Surgeons of the Hotel Dieu, a great number of medical practitioners, and the pupils that attend this hospital. This is the first *public* operation of lithotripsy performed in France*.

ANALYSES OF BRITISH MEDICAL JOURNALS.

LONDON MEDICAL AND PHYSICAL JOURNAL.

September 1829.

On the precise Seat of the Variolous Pustule. By Mr. GEORGE OAKLEY HEMING, Surgeon, Member of the Royal College of Surgeons.

MR. HEMING has paid considerable attention to the minute anatomy of the local affection in small pox and varicella, and has been led to believe that these two diseases are developed in different structures; viz. the former in the sebaceous glands and mucous follicles, while the latter is merely subcuticular.

"It may be observed," says he, "that the variolous pustule is confined to the skin and mucous membranes. After much diligent search, I have never been able to detect any thing at all resembling it in the serous membranes. I do not mean to say that there is, in no case of variola, inflammation of a serous membrane, but that I have not been able to detect any appearance of variolous pustule, or difference from that of common inflammation. Then the circular, flat, and indented form of the variolous pustule differs widely from the hemispherical form of the vesicle of varicella: it is obvious, too, from the hardness felt on an early examination, that deeper-seated parts are affected in the former than in the latter disease."

At first sight it may appear an objection to this doctrine that the variolous pustule occurs all over the body, and that several have doubted or denied the existence of the sebaceous glands over the entire surface. Beclard, however,

distinctly affirms their existence, and the late Mr. Chevalier has demonstrated their presence in every part of the cutaneous texture.

"The sebaceous glands, as is well known, are small bodies, whose office is to secrete a greasy matter, which is poured forth by their excretory ducts, and distributed over the skin; and into each of these ducts the cuticle dips. This organization cannot be discerned in the healthy state of the sebaceous glands; but, when they are diseased, it may sometimes be seen even without a lens. They are very prone to diseases, of which one form is called *acne*. It was the resemblance that this diseased state of the sebaceous glands bears to the little tumors found in the early stage of small-pox, and the striking similitude to a small-pox pustule at a more advanced period, when an herpetic eruption about the chin extends over an enlarged sebaceous gland, conjoined to other circumstances, which first led me to suppose that the sebaceous glands and mucous follicles were the parts affected by variola.

"Sir A. Cooper remarks, that some tumors arise from an enlargement of the sebaceous cysts, in consequence of their orifices being obstructed; and he observes, that 'within the cyst there is a lining of cuticle which adheres to its interior, and several desquamations of the same substance are found within the first lining.' I am now attending a young woman who has a disease of these glands, and the orifices are so much enlarged that I can pass into them a bristle. I applied a blister, and, by this means removing the cuticle, had a drawing taken of the part, in which this fact is illustrated. The sebaceous glands and mucous follicles bear the strictest analogy to each other, both in their structure and functions, and consequently are apt to be affected by the same diseases.

"I now proceed to give an account of the appearances of the perfect variolous pustule: I would first observe, most particularly, that, although the indentation of the pustule of small-pox has generally been considered by medical writers as one among many other circumstances by which we may be enabled to distinguish it from chicken-pox, it appears to me that, not being acquainted with the cause of this very curious circumstance, they have not at-

* The instrument grasping the stone, indicated on the graduated scale made for the purpose of measurement, *fifteen lines*; and the quantity of detritus expelled was sufficient to convince me that the calculus was of that size.

tached to it the importance which it seems to demand. This indentation in the pustule can only depend upon the structure of the part affected; it is the natural formation of the cuticle at that part which produces the depression in its centre.

“ Dr. Armstrong says, ‘ I have never seen the central depression absent in small-pox, and, what is remarkable, I have never seen it present in chicken-pox.’ My own practice confirms this observation; and I think that most medical men must have observed the uniformity of the central depression in small-pox. The inference I would draw is, that small-pox at all times attacks the same structure.

“ At the earliest stages of the eruption of small-pox, it is generally first seen in the hands and face, where small red spots indicate the inflamed state of the cutis. On these spots a small, round, hard tumor may be perceived by the touch, before it becomes visible. In twenty-four hours it is still more distinct. It gradually changes its form until the third or fourth day, when it is perfectly circular, with a flattened top, in the centre of which an indentation may be perceived, resembling, it has been remarked, ‘ the impression made in the skin with the head of a large pin.’ The vesicle is then about the eighth part of an inch in diameter; it is of a cellular structure, and filled with lymph somewhat turbid, and finally purulent. By the fifth or sixth day, its size has augmented to twice its former diameter. The central depression is commonly evident on the second or third day in some of the pocks, where they are numerous. Dr. Munro, in his *Observations on the Small Pox*, remarks that ‘ the central clear part of the pimple is evidently depressed on the fourth or fifth day: this depression is not to be perceived in all the pimples in the same light; but, by turning the body, it can be seen in those vesicular pimples in which it had not been previously perceptible. This fact is generally overlooked, and has often led to the denial of the existence of the central depression when it was present.’

“ There may be cases in which the central depression is not perceived without much difficulty; but, if the pustule be carefully examined by a microscope, and in a proper light, it will be discovered. It is most manifest when the

internal fluid is clear, and is essentially different from the depression in other eruptions, which exist only after the apex is encrusted. As the disease advances, a red ring shows itself round the circumference of the pustule, and becomes wider as it increases in size. There is a remarkable appearance of the pustules on the sixth or seventh day, which was pointed out to me by Dr. Marshall Hall: there is an external ring of rose colour, in which is another ring of white, evidently rendered so by the colour of the contained fluid; within this is a third ring, which is red, and has an appearance as if the surface of the pustule was in contact with the flesh beneath; and in the middle of this there is a portion which again looks white, but is dull and cloudy. These appearances I have constantly observed about the sixth or seventh day. After the seventh or eighth day, the pustule loses its indented character, and becomes nearly spherical. If it be opened, it will be found to contain pus; and not only the small sebaceous gland, which was at first merely inflamed and enlarged, has become disorganized, but all these small glands within the circumference of the pustule have partaken of this disorganization, and a slough is formed nearly of the size of the base of the pustule. A portion of coagulable lymph is thrown out around the slough; and this I am inclined to think is what Mr. Cruikshank supposes to be a membrane situated between the rete mucosum and cutis, and which he has called the membrane of small-pox.

“ Mr. Cruikshank describes this vascular membrane as situated between the rete mucosum and cutis, and which he had injected in the skin of persons who had died of the small-pox. During the summer months he macerated in water pieces of small-pox skin, which had been kept for some time in spirits, and he says, ‘ the cuticle and rete mucosum were turned down, and, upon the 8th or 9th day, I found I could separate a vascular membrane from the cutis.’ There is little doubt but this was the vascular network described by Bichat, which Mr. Cruikshank had injected, and, in consequence of the effusion of lymph which I have previously described, he was enabled to separate it in the form of a membrane.

“ From the back of a patient who died of the small-pox I removed a por-

tion of skin covered with pustules, which I macerated in water eight or ten days. I succeeded in removing the cuticle from the pustules; these still retaining their form, and being covered by another membrane. But, in the present doubtful state of our knowledge as to the existence of the rete mucosum in the white races, I found some difficulty in deciding whether this was the rete mucosum, or only a layer of coagulable lymph effused at an early period of the formation of the pustule, and subsequently raised with the cuticle by the pus contained in the pustule. Dr. Armstrong has this preparation.

“Mr. Cruikshank found that in the centre of the pustule of small-pox there was a white substance, which he could not inject; and this Mr. Hunter said was a slough formed by the varicellous inflammation. He thought it was always to be found in this disease, and that it was a circumstance by which it might be distinguished. In most cases it does exist, but I believe there are some exceptions. Upon this subject, however, I cannot speak decidedly, as I have never had an opportunity of minutely examining that kind of pustule. The cases to which I allude are those of modified small-pox, particularly as occurring after vaccination. Here we have an inflammation of a more moderate kind, and partaking more of the adhesive character. Lymph is poured out, which gives a peculiar hardness to the pustule, and, as the eruption subsides, a small tubercle is left. The lymph, however, is again absorbed, and the hardness and swelling are gradually removed. If these pustules were examined at any period, I do not think the slough would be found.”

Cases of Hysteritis Puerperalis. By JAMES PAXTON, Member of the Royal College of Surgeons in London.

This communication consists of two cases of inflammation of the uterus. The first was treated with stimulants, and afforded an opportunity of ascertaining, by post mortem examination, that the uterus was five inches in diameter, and internally of a deep crimson hue, the cervix being gangrenous. The second case was treated by means of depletion, and the patient recovered. The inferences drawn by the author are as follow:—

“1st. That copious depletion is the most powerful means of subduing inflammatory action of the uterus.

“2d. That uterine discharges have no effect in relieving that organ, when suffering under inflammation.

“3d. That neither the faintness experienced by the patient, nor even uterine hæmorrhage, or weakness of the pulse, should have any weight on the mind of the practitioner, so as to prevent his carrying local or general blood-letting to its requisite extent: for if there is fever, with constant uterine and general pain, this is the true criterion for forming a judgment of the propriety of the measure, and not any other consideration whatever.”

The conclusion, from a former Number, of Dr. Ballingall's last clinical lecture follows. We gave those parts which appeared most interesting at the time this lecture was originally published.

Case of Lithotomy; the Stone situated behind the Os Pubis. By T. HODSON, Esq. Surgeon.

Mr. Hodson thus describes the operation:—

“Upon cutting into the bladder, and introducing the fore-finger of my left hand upon the cutting gorget, I perceived the stone behind the os pubis, and so situated that it would have been impossible to have taken hold of it with the straight forceps. I therefore immediately introduced the curved forceps upon the blunt gorget, and readily got hold of the stone; but, upon attempting to bring it down, the forceps slipped and let go their hold. This happened four or five times before I could succeed in bringing it down, when it was easily extracted, and the patient, who was about forty years of age, recovered.

“The stone weighed three ounces, and was shaped like a heart, and, being situated behind the os pubis, with its apex downwards, the difficulty alluded to was readily explained; and, although the operation (as I have already observed) was finished in the course of a few minutes, it might, I conceive, have proved very tedious and embarrassing, in consequence of the stone being wedged in the arch of the pubis.”

Experiments and Observations on Mesmerism. By RICHARD CHENEVIX, Esq. F.R. and E.S., M.R.I.A., &c. (4th Article.)

The fourth article, but not the last on this subject. Mr. Chenevix has fortified himself, in the paper before us, with documents from several practitioners in London: Mr. Brodie, Dr. Prout, Dr. Holland, Mr. Earle, &c. Not one of these gentlemen, however, express any opinion that can by possibility be construed in favour of mesmerism.

October.

Historical Sketch of Lithotrity. By W. B. COSTELLO, Esq. late assistant to the inventor, Dr. CIVIALE.

Any one interested in the progressive improvements made in the art of removing calculi from the bladder, will find them well detailed in this paper. What the profession want, however, is not so much to know how badly their forefathers did these things, as to be taught the best mode in which they may be done now.

Case of Sarcocoele, in which, after the removal of one Testicle, the disease attacked the other, and was cured by the use of Bougies. By JOHN NORTH, Surgeon, F.L.S.

This case is interesting: we shall therefore give it full.

In many cases it may be difficult to determine whether the removal of disease is to be attributed to the efficacy of the treatment which is employed, or to some spontaneous operation of nature. I think, however, it may fairly be inferred that the successful termination of the second attack, in the following case, was owing to the means which were adopted.

A gentleman, 26 years of age, who had previously enjoyed uninterrupted good health, felt for some weeks a slight tenderness of the left testicle. He attributed it to cold or fatigue, or some accidental and trifling cause, and paid little or no attention to it. For two months the pain of the testicle continued to increase, but as yet it was not very severe. The part was slightly enlarged. In this state he applied to me. I could not, after the strictest examination, ascertain any probable cause

upon which the local affection might be dependent. He had not for many years had gonorrhœa, and had never any symptoms of stricture. He was directed to remain as quiet as possible, and to confine himself to a mild regimen. Leeches were applied to the part, and afterwards fomentations. Occasional purgatives were given, and small doses of calomel, combined with extract of hemlock, twice a day. A large-sized bougie was also introduced into the bladder, to determine that there was no obstruction in the urethra.

Under this treatment the pain almost entirely ceased for a few days. The testicle, however, continued to enlarge, and it had now an irregular feel. Under the direction of two eminent surgeons, various means, both general and local, were had recourse to, but without avail. The pain and swelling of the part slowly increased for three or four months, and as the health of the patient was visibly declining from constant suffering, and every mode of treatment had been adopted from which relief could be rationally expected, it was deemed expedient to remove the testicle. It was now at least six times the natural size, and exquisitely painful. The colour of the scrotum was darker than natural. The patient cheerfully consented to the proposal, and the operation was performed.

Upon examining the testicle after its removal, it was found to be completely altered in structure. It presented the appearance of a scrofulous mass. In some parts it was very firm, in others comparatively soft. There was a very small quantity of fluid in the tunica vaginalis.

After the operation the patient speedily rallied, and in the course of a few weeks he was capable of pursuing his accustomed avocations. His health and spirits were completely restored.

About four months from this period he perceived, in walking or riding, a very trifling uneasiness in the right testicle, which would not probably have attracted his attention, had he not been taught by his former experience the necessity of timely precaution. He came to town immediately, in a state of much anxiety. I examined the part attentively, and found that it was tender to the touch, and rather harder than natural. It was nearly double the ordinary size; but it was at first doubtful

whether this circumstance was to be attributed to disease, as, after the removal of one testicle, the other frequently becomes much enlarged. Mr. Heaviside, who had before seen the patient, was again consulted.

It would be useless to detail minutely the different local and general remedies that were employed. It was evident that the disease was gradually gaining ground, and that it was pursuing the same course as the former. A slight and very temporary amendment, indeed, was perceived while he was under the influence of a mild course of mercury; at which time, hemlock poultices were also applied to the part.

Mr. Guthrie's opinion was now taken. The testicle was about four times the natural size, and very painful on the slightest pressure; the general health of the patient bad; his mind, of course, anxious and dispirited. Mr. Guthrie recommended the continuance of decoction of sarsaparilla and the compound calomel pill, which he had been before taking; in addition to which, he directed that a large-sized metallic bougie should be passed three times a week, and kept in the urethra for several minutes.

Considerable irritation was produced by this treatment along the whole course of the urethra, and a slight scalding in making water. For the first few times a trifling hæmorrhage also followed the use of the bougie. In the course of a fortnight the size of the testicle was evidently diminished, and there was much less tenderness on pressure. The use of the bougie was continued for nearly three months, and during this time the swelling of the testicle, the pain, and indeed every appearance of disease, gradually subsided. The patient could take active exercise without the slightest uneasiness.

Several years have now elapsed since the occurrence of the disease. The gentleman has enjoyed perfect health, and is in full possession of the power of which he was once so much in danger of being altogether deprived; for there was every reason to fear that the remaining testicle must be removed.

It was the opinion of the late Mr. Ramsden, that some cases of sarcocele might be relieved by removing, with bougies, a morbid irritability of the urethra, which he presumed, theoretically, to be sometimes connected with

the origin of the complaint. Whether the case I have related tends to support this doctrine, I will not venture to determine. The efficacy of the practice to which it leads cannot, I think, in this instance, be doubted.

Mr. Cooper*, in commenting upon the use of bougies in cases of sarcocele, as recommended by Mr. Ramsden, remarks, "the novelty of this suggestion for a time attracted considerable notice; but the interest which it once excited has now died away, a sufficient proof to my mind that the practice inculcated was not of much value." Unless I am mistaken, Mr. Cooper much underrates the confidence which the most competent surgical authorities still place in the treatment suggested by Mr. Ramsden, although it may not, perhaps, be in such general use as to render an additional proof of its *occasional* efficacy altogether superfluous.

It is remarkable that the brother of the gentleman whose case I have related was afterwards attacked with a similar disease, in consequence of which it became necessary to remove both the testicles. He died of pulmonary consumption. I am unacquainted with the progress of the disease, or with the treatment that was adopted in this case.

—

On the Use of Nitrate of Silver in Vaginal Discharges. By GEORGE JEWEL, Esq.

After observing on the distressing nature of vaginal discharges, and the error in practice which the common appellations of "whites" or "weakness" are calculated to produce, Mr. Jewel continues—

"It would appear, from a strict investigation into the numerous causes of leucorrhœal complaints which have fallen under my observation, that one uterine affection gives rise to vaginal discharge more frequently than any other—namely, a subacute or chronic inflammation of the cervix uteri. I am disposed to believe, also, that very many of such cases are mistaken for carcinoma uteri, and that, in consequence, either no remedies are prescribed, or a very inefficient mode of practice is adopted. I am aware that, in many cases, the train of symptoms

* Surgical Dictionary, fifth edition, p. 1061.

about to be noticed may be attributed to an irritable condition of the uterus, so ably described by Dr. Gooch. I cannot, however, easily relinquish the opinion I had originally entertained upon the subject, namely, that inflammation, either of the chronic or sub-acute kind, of the cervix uteri, is, in the majority of cases, the exciting cause of vaginal discharge. The distinction, however, although pathologically recognized, cannot, I conceive, be material in practice: indeed, this will be obvious to the talented author himself, whose mode of practice, in cases of irritable uterus, appears precisely applicable to cases of chronic uterine affections generally. Again, in some cases it may be difficult to discriminate between such diseases as I have alluded to, and incipient scirrhus disorganization. The following remarks will probably assist the young practitioner in his diagnosis.

This inflammation of the cervix uteri, like scirrhus or other organic disease of the uterine system, attacks occasionally at the period of life when the catamenia are about to cease; but I have more frequently found it to exist in married women, from the age of twenty-six or twenty-seven to that of forty, and very recently I have seen several severe cases occurring in young married females, within three months after the birth of the first child. The local symptoms in both diseases are very nearly allied, namely, occasional lancinating pain, more or less acute, through the region of the uterus; with a constant dull kind of pain about the inferior portion of the sacrum, the hip, or groin; attended also by an irritable bladder, or frequent desire to void the urine, and in some severer cases by tenesmus. The vaginal discharge is of a milky or cream-like colour, and is commonly, but particularly in the more acute cases, mixed with a dark-coloured or grumous secretion. Upon making an examination per vaginam in this disease, the os uteri will not be found open to the same extent as in carcinoma, nor will its margin present the same cartilaginous hardness to the touch. The pain does not appear to be situated in the edges of the os uteri, as described by Mr. Burns, but in the cervix, as pressure upon this part alone occasions the patient to complain. The uterus will be found projecting lower in

the vagina than natural; but this will depend upon the nature of the complaint: the more acute, the farther it will have descended.

"It is not my intention to dwell upon the routine practice usually had recourse to in uterine diseases; such as the local abstraction of blood, perfect rest, narcotics, the warm bath, &c.; but rather to draw the attention of the profession to a therapeutical agent, which I believe has never, or to a very limited extent, been employed in such cases, namely, the nitrate of silver applied directly to the part affected; a practice which I have been led to adopt from having so frequently witnessed the extensive and healthy changes which have resulted from the application of this remedy to the different mucous tissues, when their secreting surfaces had taken on a disordered or unhealthy action. The mode I have adopted in its application has been either to conceal it in a silver tube, precisely upon the principle as it is employed in cases of stricture, (except that the tube should be adapted to the size of the caustic,) or in the form of solution, in the proportion of three grains to the ounce of water, the strength being gradually increased. A bit of sponge, firmly and neatly tied to a piece of whalebone, is to be moistened with the solution, and carefully introduced into the vagina up to the os and cervix uteri. This mode of application is preferable to the injection, and can easily be effected by the patient herself. The application should be frequently made, or no permanent good can be anticipated."

Some cases are given in illustration, and the author concludes by remarking, that, though he by no means supposes that the diseases of which he treats are to be eradicated as if by magic, yet that he knows of no remedy so likely to afford such immediate and permanent relief.

On the Adulteration of the Hydriodate of Potash. By J. PEREIRA, Esq. F.L.S. Lecturer on Chemistry and Materia Medica, &c.

Mr. Pereira suspects that adulterations of the hydriodate of potash are frequently practised, and if so, the circumstance will account for much of the contradictory testimony with regard to it. The following extract contains an

account of the modes he proposes of detecting impurities;—

“ The substances most likely to be met with are the carbonates, sulphates, and muriates, which may be detected thus:—

“ 1. If the *carbonates* are present, they may be known by lime-water, muriate of barytes, or sulphate of magnesia, producing a white precipitate in a solution of the suspected salt, soluble with effervescence in muriatic acid. Sugar of lead also produces a white precipitate, which effervesces on the addition of muriatic acid; chloride of lead being precipitated.

“ I would, however, here remark, that if any of the above precipitates be small, and the quantity of fluid large, the effervescence may be hardly, or not at all perceptible, owing to the solution of the carbonic acid in the fluid.

“ It may happen also, that although the hydriodate is adulterated with the carbonate of potash, yet the white precipitate produced by muriate of barytes may not be *wholly* soluble in muriatic acid, owing to the carbonate of potash of the shops usually containing some sulphate mixed with it.

“ 2. The *sulphates* (as of soda) may be detected by a solution of sulphate of magnesia producing no precipitate; but a solution of muriate of barytes produces a heavy white precipitate, insoluble in muriatic acid. This adulteration is, I believe, very rare.

“ 3. The *muriates*, according to Chevallier and Robiquet, are frequently present. Indeed, the latter chemist states that they may be one of the results of the operation to form the hydriodate. The peculiar saltish taste would lead us to suspect the presence of either muriate of soda or of potash. However, we may determine this chemically.

“ Add a solution of nitrate of silver to the suspected solution, and a yellowish white precipitate will fall down; to which add excess of liquor ammoniæ, and stir the mixture. After letting it stand for a little time, filter. If the filtered liquid throw down a white precipitate on the addition of nitric acid, the suspected salt contained a muriate.

“ The theory of this process is very simple. Nitrate of silver throws down, in a solution of the pure hydriodate, a yellowish white precipitate of iodide of silver, *insoluble* in ammonia. From the solution of a muriate, the nitrate of

silver throws down a white precipitate of chloride of silver, *soluble* in ammonia. Hence, then, when a solution of nitrate of silver is added to a solution of the hydriodate adulterated with a muriate, we obtain a precipitate consisting of the iodide and chloride of silver. Ammonia dissolves the chloride, but leaves the iodide. When the liquid is filtered, and an acid is added, the chloride of silver is precipitated.”

Experiments and Observations on Mesmerism. By RICHARD CHENEVIX, Esq. F.R. & E.S., M.R.I.A. &c. (5th and last article.)

This paper consists chiefly of a memorandum from Dr. Elliotson, who, we are informed by Mr. C., devoted a considerable share of attention to the experiments he made while in London. Part of Dr. Elliotson's narrative runs thus—

“ A fourth patient was now seated in the chair. She exhibited no apprehension of any kind, but was talking very cheerfully to me. Mr. C., without saying one word to her, began his manipulations, at the distance of half a foot, but did not touch her. In about one minute she said, in a plaintive voice, “ Sir, don't do that;” and seemed in great distress. She afterwards told us that Mr. C. drew weakness into her, and made her feel faint. She complained of pain in the abdomen. Mr. C. moved his hands transversely before it, and she said the pain was gone. (She had felt a slight pain there before we saw her). She then complained of great uneasiness in her chest; and after some transverse movements, made by Mr. C. with the intention of removing it, she declared it was gone. The pain in the abdomen returned, and ceased, as before, by the manipulations of Mr. C. Mr. C. then darted his open hand towards one arm, without touching it, and told her to raise both arms. She scarcely could move that which he had thus mesmerised. He then made some transverse passes before it: she at once moved it, and declared the stiffness and uneasiness to be gone. The same was repeated with the other arm, and with the same effect. He told her to lift her feet: she did so with perfect ease. He then darted his hand toward one leg, and she stared with astonishment at finding that she could not stir it without the greatest difficulty. He then made some trans-

verse passes, when she instantly raised it, and said there was neither pain nor stiffness in it. He then closed her eyes, and put a very small piece of paper, weighing perhaps one grain, on her foot, in such manner that it was utterly impossible she could perceive it: she could scarcely move that foot. The paper was removed in the same manner, and without her knowing it: she could instantly raise her foot. She now complained of pain about the heart: Mr. C. demesmerised her, and she said it was gone. In all these experiments, Mr. C. had most clearly announced to me, in French, what his intentions were; and the effects coincided so accurately with those intentions that I confess I was astonished. Deception was impossible. Mr. C. looked round at me, and asked, in French, if I was satisfied. I really felt ashamed to say no, and yet I could scarcely credit my senses enough to say yes. I remained silent. He then asked me, still in a language unintelligible to the patient, 'Shall I bring back a pain or disable a limb for you once more?' I, of course, requested that he would do so. He complied instantly, giving her a pain in the chest once, and disabling her several times from moving her limbs, and removing those effects at pleasure, according to the intentions which he announced to me; the whole taking place exactly as it had done in every former trial on this woman. As, however, she began to feel faint and uncomfortable, Mr. C. judged it prudent to desist; assuring me that such experiments as these should never be repeated, but with moderation, and only by experienced mesmerisers.

"On questioning this woman a few days after Mr. C. had produced such decided effects upon her, respecting what had occurred, she declared that he had disabled first one limb, then another, and restored their use, exactly as appeared to be the case; that she never had felt any thing like it in her life before: that, though she had not slept during the operation, she had felt very drowsy; that she had not been at all afraid; but, said she, 'I hope never to see that doctor again, as I am sure he has something to do with the devil.'"

Mr. Chenevix began this series of papers by declaring that "mesmerism is true"—a position from which we were compelled to dissent. He concludes them by stating that "mesmerism is

true—or false," a mode of putting the proposition so ingenious that no one can possibly avoid coming to the same conclusion.

MEDICAL GAZETTE.

Saturday, Oct. 31, 1829.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."—CICERO.

IRISH APOTHECARIES.

THE late proceedings in Apothecaries' Hall, Dublin, of which we gave a most condensed account in our last number, were of so singular a character, that it may be permitted us shortly to revert to them. That the parties were in earnest, and had some real grievances to complain of, notwithstanding the strange scenes which were enacted on the occasion, we are by no means disposed to doubt. This advantage, at least, they would seem to have gained, that their tumultuous and somewhat whimsical altercations have called the public attention more directly upon them, than, perhaps, a more quiet and orderly mode of proceeding could possibly have effected. And we shall ourselves take this opportunity of stating some facts which have come to our knowledge, relating to the past and present state of the Apothecaries' profession in Ireland.

The number of licensed Apothecaries in Ireland is calculated at about a thousand, and their qualification as regular practitioners is derived from a governing body, entitled the Apothecaries'-Hall Company. Of the origin and constitution of this Company, we mean to enter into a short detail, the better to understand the nature of those imperfections which have been so boldly charged upon them, and we shall then

see what measures have been proposed for their remedy. It is to be regretted, that in the heat of disputation, excited at the late meetings, those abuses were so unqualifiedly attributed to persons, which are, in truth, only chargeable on a system originally ill constructed; there is, however, some satisfaction in being able to add, that since those angry discussions, the principal "assertor" has come forward and offered every apology for his unfounded imputations, even to the tendering of a written *amende**. The mutual concessions, indeed, which have led to the miraculous union resulting from these meetings, augur the most favourable issue to the arrangements in contemplation.

It may well be conceived, that no attempt was made in Ireland to regulate the profession of pharmacy until necessity called loudly for it; and, in fact, 40 years have not quite gone by, since the art of the apothecary existed in the most deplorable condition in that kingdom. Fraud was added to ignorance; and that too in a calling in which ignorance alone was but too often fatal. Not always had the patient so good a chance of escape as when a certain sick man was well exercised in a *wheelbarrow* after a dose, in consequence of the concluding phrase of the prescription being "*e quovis idoneo vehiculo.*" Instances of this kind were not rare in Ireland. But it is needless more particularly to exemplify the state of things at the period to which we allude; suffice it, that the country swarmed with the most impudent and dangerous pretenders.

Yet a few—a redeeming few—were found, who felt the necessity of forming a union for the protection of themselves and the community. They combined in the form of a joint-stock company, and obtained from Government an act of incorporation, which professed

to arm them with full powers to reform and regulate their profession. Our lawyers and framers of laws are not always the most clear-sighted people in the world; whether from actual or pretended incapacity we will not positively affirm, but true it is that here, in this incorporating instrument, were a loop-hole or two, quite large enough, as it turned out, for a coach and six to be driven through them. It was soon discovered that from a remarkable omission in the wording of the act, its main object was well nigh abortive. For instance, after a copious detail of very unexceptionable arrangements with regard to seven years' apprenticeships, without which it was intended that no man should exercise the art or mystery of an apothecary in Ireland, it was further ordained that previously to his opening a shop he should be examined at the Hall, to give proof of his competency. But singular to relate, it was altogether omitted that the candidate for such examination should have served any apprenticeship at all. The clause to which we allude—the 23d of the Act of Incorporation, barely states that "no person shall open shop, or act in the art or mystery of an apothecary in Ireland, until he shall have been examined as to his qualifications and knowledge of the business, and the examiners shall grant or refuse him a certificate." Strictly, then, according to the letter of the law, and according to some of the best opinions, it appears that any candidate, no matter whether he have or have not served an apprenticeship, is entitled to, nay, can demand and insist upon an examination. Whatever may have been the spirit of the legislators and framers of the bill on the subject—and we can hardly suppose them capable of such gross absurdity as the literal acceptance of the clause would imply—the door was thus opened to very glaring abuses, and the apo-

* Mr. Kenny, of Waterford: see the public prints.

thecary's profession in Ireland reduced to a state of the utmost degradation—affording a practical illustration of the effects of the *non-certificate* system, so strenuously contended for by some wiseacres in this country.

It might indeed be asked whether a strict examination before the Directors of Apothecaries' Hall would not afford sufficient protection to the public without apprenticeship? But unfortunately a satisfactory examination can hardly be enforced, for here again the act presents us with another of its peculiarities. It is further enacted, that "if any person who has been examined by the Directors of Apothecaries' Hall, and rejected, shall think himself aggrieved, he may appeal, first, to a general council of Apothecaries' Hall, and afterwards to the College of Physicians, who shall re-examine him, and affirm or reverse the judgment of the Council." This is a stumbling-block indeed: the Directors must either pass the candidate in the first instance upon evidence of his capability, perhaps not satisfactory to their consciences, or run the risk of having their decision reversed by a higher tribunal; and by a tribunal too of whose competency to determine the candidate's "qualification and knowledge of the business," they are naturally inclined to express their doubts. Whether their doubts be well founded or not, we shall not now stay to inquire, sensible as we are of the influence which a certain *esprit de corps* must always exercise in such considerations; but we think it obvious that prudence should prompt them to avoid, if possible, the obnoxious alternative.

In consequence of these arrangements, the most serious abuses were gradually introduced. An apprenticeship was deemed unnecessary—it seemed to be an expensive mode of proceeding, and not legally requisite. Many who never regularly served a

day in an apothecary's establishment demanded an examination, and their license; while many opened shops without any license whatever.

The probability of the occurrence of cases so flagrant as this last, was, of course, provided against by the act of parliament, but in a manner the most inefficient and inadequate. The Company were empowered to recover 20*l.* penalty against the offender in any of his Majesty's courts of law in Dublin. The penalty might, for instance, be recovered in the King's Bench, with considerable costs; but it did not follow that either penalty or costs would or could be paid by the defendant; the Company were generally the sufferers in such prosecutions. Yet, notwithstanding the inadequacy and absurdity of this protection, the Apothecaries' Hall did, in numerous instances, and at great pecuniary risk, vindicate their privileges; and attempt a reformation. The offenders were still gaining ground, and promising to support each other in offering a powerful resistance to the "monopoly," as they were pleased to call it, of the Apothecaries' Hall; but the verdict of a jury proved decidedly unfavourable to their views, and induced them to adopt a new line of proceeding. They accordingly got up a petition, and had it presented to the House of Commons during the last session. Some of the statements in this document are curious: we shall just point out a few of them, and avail ourselves of the observations of Mr. Donovan, contained in his recent pamphlet on the State of Pharmacy in Ireland*.

"The title sets forth that it is 'the petition of the *physicians, surgeons, and apothecaries* of the north of Ireland.' This title will, no doubt,

* Reflections on the Present State of the Profession of Pharmacy in Ireland, by M. Donovan, M.R.I.A. Dublin, 1829.

be admitted to be very astute, when it is considered that it aims at giving the weight of three different branches of the profession to the petition; and when it is understood that it is not the petition of any physician, any surgeon, or any apothecary, but of a set of men who each in his own proper person professes to combine the three departments; but as these persons hold no license, they are but *soi-disant* apothecaries*.”

To the charge “that from the period of incorporation until rival establishments arose in Dublin, the Company made no effectual effort to enforce the provisions of the act, or to benefit the profession,” Mr. Donovan replies very satisfactorily. He repels the insinuation that the prosecutions commenced by Apothecaries’ Hall against the unqualified apothecaries of the north of Ireland were instigated by selfish or unworthy motives; he shows the absurdity of supposing that any establishment in that country could rival the Company of Apothecaries’ Hall; and he states it strongly, that so far from tamely looking on at the progress of abuses, they have since the period of their incorporation, in the year 1791, taken law proceedings for the purposes of punishment in no less than 473 instances. “This astounding assertion of the petitioners,” says Mr. Donovan, “was even ventured upon as a defence at the late Carrickfergus trial of the Hall Company against a gentleman for practising as an apothecary without a license; but it met with the deserved censure by a ready contradiction from the Bench, for the learned judge declared that he had presided at one of these trials himself some years before, in which the Apothecaries’ Hall Company were successful.”

The petition concludes with something like a proposal to parliament,

that the profession of an apothecary should be thrown open to all persons who obtain diplomas to practice in other departments from the British Universities and Colleges of Physicians and Surgeons. On this head Mr. Donovan’s remarks appear to be so judicious, that we shall find room for one or two more extracts.

“I shall now assign reasons for believing that the profession of an apothecary should not be thrown open to the public; that the adoption of it should be placed under some restrictions, and that a monopoly in the profession, to a certain extent, is conducive to the welfare of society. This can be done by an illustration easily understood. If any department of trade—say, for example, cloth weaving—were confined to one manufacturer, there is no doubt but that the interests of the community would suffer: the consumer would have no alternative between the purchase of whatever quality the manufacturer thought fit to impose on him, or doing without the article altogether. The utility of establishing a second, third, or any reasonable number, is, in this case, manifest; by competition, the article is improved in quality or reduced in price. Suppose that the competition is so great as to reduce a certain quality of cloth to its *minimum* price. By further competition, the price may certainly be further reduced, but the quality must be deteriorated. Here, however, but little injury is done to the public, for the bad quality of the cloth discovers itself; it speedily wears out, changes its colour, tears, and, in fine, evinces to the purchaser that he derives no real advantage from this apparent reduction of price. This point once established, the evil produces its own remedy. But a moment’s reflection shews that this cannot be the case with regard to compounded medicines. Moderate competition will do some service in this case also, but when it becomes inordinate, it ceases to be a benefit. Let us suppose, as in the former case, that by competition the price of compounded medicine is reduced to its *minimum*, the quality being the best. Competition may still reduce the price, and deteriorate the quality as before;

* Reflections, p. 18.

but here the analogy ceases; for in the case of compounded medicine the consumer can never discover the badness of its quality; there is no criterion; its failure to produce beneficial effects on the animal economy is none, for the best quality might also fail, and how is it to be decided whether the failure is attributable to the inefficiency of the medicine or the obstinacy of the disease? Nay, the physician who prescribes it is as much in the dark. But besides these effects of competition, it may happen that the total business to be done in a district may be so divided amongst the competitors, that, although the little that remains to each may be well paid, still the apothecary, at the winding-up of his year's accounts, may find that his business is below his notice. Will he, then, faithfully and attentively serve the public, when it is made his interest to act otherwise, and when dereliction from duty can certainly escape detection, unless he is a man of inflexible moral sense? It would not become me to answer the question: let every one decide according to his experience of mankind. In fine, though it is a common maxim that competition is the life of trade, there could be no greater mistake committed than to apply the principle to the compounding of medicine: it is a death-blow to the dearest interests of society. The competition will affect the scale of charges only, and not the excellence of stock*."

But we must conclude. It only remains to be inquired what means should be adopted for the purpose of regulating the profession of the apothecary in Ireland. The legislative body, in whom the power, to a certain extent, resides, seem to be aware of their absolute inability to give satisfaction to all parties. That they have not been quite fairly dealt with, we have little doubt; and the very circumstance, as we remarked in our former observations, that the most opposite and contradictory charges have been made against them, ought rather to weigh in their favour. A party in the North of Ireland have complained

to parliament that they are persecuted with vexatious prosecutions; but a party in the South are complaining much more loudly that these prosecutions are not half numerous enough, and that they should have commenced long before. This clashing of opinions and opposite interests, however, is very far from proving that the present governing body should be abolished; though it may forcibly demonstrate the necessity for a reform. Constituted as the Apothecaries' Hall Company is at present, it is peculiarly open to objections. It consists nominally of sixty persons, or shares; but these shares, it seems, may be so disposed of (four to one person, for example), that the actual number of members constituting the company may be reduced to fifteen; a narrow monopoly, in all conscience, to be entrusted with the regulation of the whole profession. Mr. Donovan's plan is to increase the number of shares to eighty; and he advises that each of these be conjointly possessed by five individuals: thus the number of proprietors will be extended from sixty to four hundred. The proposed arrangement is said to have given universal satisfaction; and, indeed, we should think that it ought to satisfy even the boldest advocates for "throwing open the monopoly."

MR. LAWRENCE'S LECTURES.

THE rage of the Editor of the *Lancet* at the continued and increasing success of this Journal, knows no bounds. His vocabulary of abuse is in constant requisition, and in this respect we are fain to own ourselves his inferiors. We mentioned, a fortnight ago, that he had repeatedly insinuated that Mr. Lawrence guaranteed the accuracy of his lectures as they appeared in that Journal; and knowing this to be false, we published to the world that it was so, and dared the Editor of the *Lancet* to contradict. This worthy meet our

* Reflections, &c. p. 25-28.

defiance?—just as we expected. He links the question altogether as regards himself, and turns it off by saying, that, at all events, Mr. Lawrence does not correct them in this Journal. Who ever said that he did? We hold it to be contemptible and dishonest to throw upon another the burden which properly and exclusively belongs to our reporter and ourselves.

It may, perhaps, be said that Mr. Lawrence did formerly correct certain lectures of his which were published in the Lancet, and therefore may again. There is, however, this essential difference between the cases: Mr. Lawrence had his lectures on the Eye written out and fully prepared for publication, so that he could have no motive for wishing to avoid rendering himself answerable for the opinions they contained; but in the present case he has not his lectures written, and therefore, *we believe*, that but for his apprehension that the Lancet would publish them at all hazards, he would not have suffered them to meet the public eye at present in any of the Journals. We positively aver, then, that the insinuation that Mr. Lawrence corrects the press of his present lectures in any of the Journals is an unworthy trick to promote the sale of the work at the expense of the Lecturer's reputation; and which, if persevered in, will probably call forth some more decided denunciation of its falsehood.

We also stated that Wakley had the impudence to advertise the publication of Mr. Lawrence's lectures without informing that gentleman of his intentions. This the Lancet says is "a lie" (we like to give the precise words), and yet this we deliberately repeat. In the early part of September a puffing advertisement of the Lancet, in which that Journal was designated as "unparalleled," "unrivalled," and "unequaled," went the round of the provincial papers, especial care being taken that it did not appear in the London press; and in which, among other things, was announced the publication of Mr. Lawrence's lectures. In these advertisements it was not stated that Mr. Lawrence's consent had been obtained, nor was this addition made till the very end of the month, when our advertisement was already in circulation. Will Wakley venture to say that Mr. Lawrence was aware of his intentions

when he published these first advertisements in the country? If he does, we have an answer ready.

NEW REGULATIONS OF COLLEGE OF SURGEONS.

(Confirmed October 29).

Regulations respecting the Professional Education of Candidates for the Diploma.

I. Candidates will be required to bring proof

1. Of being twenty-two years of age.
2. Of having been engaged six years in the acquisition of professional knowledge.
3. Of having studied Anatomy, by attendance on Lectures and Demonstrations, and by Dissections, during two anatomical seasons.

An anatomical season is understood to extend from October to April inclusive.

4. Of having attended two courses of Lectures on Surgery, each course comprising not less than sixty Lectures.
5. Of having attended Lectures on the practice of Physic, on Chemistry, and on Midwifery, during six months; and on Botany and Materia Medica during three months.
6. Of having attended during twelve months the surgical practice of a recognised Hospital in London, Dublin, Edinburgh, Glasgow, or Aberdeen; or for six months in such an Hospital, and twelve months in any properly constituted provincial Hospital, acknowledged by the Council as competent for the purposes of instruction.

It is earnestly recommended that Candidates shall have studied Anatomy, by lectures, demonstrations, and dissections, for one anatomical season prior to their attendance on the surgical practice of an hospital.

II. Members and Licentiates in Surgery of any legally constituted College of Surgeons in the United Kingdom; and Graduates in Surgery of any University requiring residence to obtain Degrees; will be admitted for examination on producing their Diploma, License, or Degree.

N.B All Certificates recognised by the Royal Colleges of Dublin and Edinburgh, or by the Universities of Glasgow and Aberdeen, as to attendance on Hospitals or Lectures in these places respectively, will be received.

ONE OF WAKLEY'S WITNESSES.

In another part of the present number will be found a report of the action of

the King *versus* Clapham. This unfortunate young man was one of the witnesses brought by Wakley against Mr. B. Cooper, and his history affords a striking lesson to those who imagine that they can form disreputable connexions without the risk of their principles being contaminated, their characters blasted, and their prospects in life destroyed.

MEDICO-CHIRURGICAL OMNIBUS.

To the Editor of the London Medical Gazette.

SIR,

I AM sure your readers will rejoice to learn that it is in the contemplation of the Council of the Medico-Chirurgical Society, in consequence of the extreme thinness of its meetings, and the complaints made of the inaccessibility of the society's rooms, to establish an *omnibus* in its service, for the express purpose of bringing members, with cheapness and facility, to its meetings; the greater portion of the members having no carriage, and most of those who have one not caring to use it at night. The following has been handed about as an outline of the scheme intended to be proposed for the adoption of the society.

That the *successful* members be requested to make over their cast-off carriages to the treasurer, who will contract with some cheap coach-maker to unite them together, so as to form one long coach, after the manner of an *omnibus*; which title it is to bear from the circumstance of its being intended to convey indiscriminately physicians, both fellows and licentiates; surgeons, hospital, military, and common; accoucheurs, whether doctors or misters; apothecaries, high and low; in short, in it is to be the *omnium gathering* of the profession. No seats will be set apart for knights and baronets even, but "first come first served" is to be the motto of the vehicle.

The *accoucheur* members, being most in the habit of driving, and knowing the streets best, are to be requested to lend their aid in rotation, each as *coachman* for the night. Their habits

of *delivery* afford the best chance of exactness and punctuality in setting down and taking up, and the management of parcels on the way. The honorary secretaries have already volunteered their services in turn, each as *conducteur* for the night; and it is proposed that one of the council shall always attend as *cad* to the Omnibus.

The coach is to start with one horse, from a given point at the West end of the town, at eight o'clock on the nights of the meetings, and to take a circuit through the principal streets (to be named hereafter) at a moderate pace, the *cad* knocking at the door of each member on the way, and receiving sixpence a head for the accommodation, to be placed to the funds of the society, out of which there is to be provided *tea* and *coffee* at the meetings, that the members may not urge the interruption of their evening refreshment as an excuse for non-attendance. At the breaking-up of the meeting, the Omnibus, with its live cargo, will return by the same route which it followed in coming.

The advantages of this plan will at once combine utility, economy, and convenience. A *reunion* of the profession, so much desired, will thus be formed, and an opportunity given for the discussion of professional topics *en route*, and, like the ancient peripatetics, we shall possess an ambulatory source of improvement and reasoning. A sort of flying conversation will be kept up fortnightly, and the scruples of many worthy and respectable members of the pedestrian order (for, as Horace says, "some slay in chariots, some on *foot*,") respecting being seen among the purlieus of Drury Lane, and elbowing the company at the *soirées* round the gin-shops of Holborn, will then be set at rest, and general satisfaction afforded.

The social advantages to the profession, from this plan being adopted, are indeed incalculable; and no doubt can be entertained of the moral influence it will have upon us, by thus amalgamating the *exclusives* and the *odd ends* of the profession together, and jolting them into harmony and good humour with each other. The public also will gain by this arrangement, for the nights on which the Medico-Chirurgical Omnibus passes along being known, visits, appointments, consultations, &c. may be easily made, and five minutes

will be allowed every passenger for visiting a patient on the road before nine o'clock, and after the meeting, till midnight.

We may now congratulate the society on the prospect held out of its recovering its falling reputation and interest, and we have no doubt of its coming again into fashion, by the magic influence of the Omnibus, which will directly tend to remove all the serious objections to the society on the score of its locality and the abominable approaches to its rooms. As the society will not move to a more accessible spot, some such means as here detailed certainly become necessary to entice members to give their time and talents as well as money.

Your constant reader,
MEDICO-CHIRURGUS.

October 26, 1829.

PROCEEDINGS OF SOCIETIES.

MEDICO-CHIRURGICAL SOCIETY,

October 27.

Dr. Lee's Paper on Uterine Phlebitis and Phlegmasia Dolens.

In a former communication which Dr. Lee presented to the Society, on the pathology of phlegmasia dolens, he was led, from various facts, to infer that inflammation of the iliac and femoral veins gives rise to all the phenomena of that disease in puerperal women. Subsequent dissections have enabled him not only to confirm the accuracy of the former observations, but have led him to discover the important pathological fact, that in phlegmasia dolens the inflammation commences in the uterine branches of the hypogastric veins, and subsequently extends from them into the iliac and femoral trunks of the affected side.

The object of the present communication was to submit the different facts which have led him to this conclusion, and to detail the observations he has made on inflammation of the uterine veins.

In the first of the cases he detailed, there succeeded, after a short interval, to the usual symptoms of phlegmasia dolens, those which characterise phlebitis in its severest forms, viz. rigors, prostration of strength, rapid feeble pulse, low

wandering delirium, attacks of vomiting and diarrhoea, with brown parched tongue, and ultimately rapid and destructive inflammation of the eyes, and purulent deposits in the substance of the lungs. Morbid appearances were also observed in the veins, demonstrating that the alterations in the structure of that system of vessels were produced by inflammation; and further, that the right iliac veins were affected at a much earlier period than the vena cava, and those of the left side. The veins of the right side were partially obliterated, and the principal changes they had undergone appeared to be of long standing, and to be perfectly distinct in respect to the period when they had taken place from those observed in the other veins, and to be referable to the effects of a former attack of phlegmasia dolens.

Though the branches of the hypogastric veins were not traced to the uterus, in consequence of the unfavourable circumstances under which the dissection was made; and although no sign of recent disease could be perceived in the tissues of this organ, yet from the complete obliteration of the trunks of the hypogastric veins, and the contracted and reduced state of their coats, it may be reasonably supposed that their branches were similarly affected, and that the disease originated in them.

The history of the second and third cases, and the morbid alterations of structure observed in the iliac, femoral, and hypogastric veins, demonstrated that these changes were the result of inflammation, and that this inflammation had commenced in the uterine plexus of the hypogastric veins, and extended along their internal membrane to the great venous trunks of the pelvis and inferior extremities.

Dr. Lee next adverted to a case of obliteration of the vena cava and its principal branches, after parturition, recorded by Mr. Wilson, where the inflammation which had produced the morbid appearances was found to have commenced in the uterine veins. "The coats of the emulgent veins, and of their branches, were thickened, and their cavities filled with coagulable lymph. Both the spermatic veins were remarkably thickened, and their cavities completely obliterated; as were the primary iliac veins until they had nearly reached the groin, and the internal

iliac veins, with most of their branches, particularly those which returned the blood from the uterus. The uterus was much larger than usual, the coats of its principal veins were thickened, and their cavities partially obliterated. The small branches, both in its substance and in its internal surface, were very numerous, and much distended with blood. The vessels of the lower extremities were in a perfectly healthy condition; no accumulation of blood had taken place in the veins, nor had any watery fluid collected in the cellular membrane."

The anastomosing branches of the veins on the sides and back part of the pelvis were much enlarged, as were also those between the vena saphena major and the branches accompanying the deep-seated arteries passing through the foramen magnum ischii and the sciatic notch: large communications existed between the *vênæ pudicæ externæ* and the lower branches of the inferior mesenteric vein, which was enlarged to treble its natural size.

Two other cases of a similar description are mentioned by Mr. Wilson, in both of which the veins of the uterus contained pus*.

As none of the symptoms of phlegmasia dolens were present in either of these cases, and as neither pain nor swelling occurred in the left inferior extremity of the patient whose case was first detailed, though the common and internal iliac veins were both completely impervious, it would seem to follow that it is essentially requisite to the production of the disease that the inflammation should extend from the iliac into the principal veins of the extremity. In all the examples of phlegmasia dolens which have come under the observation of the author, this extension of the inflammation has been distinctly marked by increased sensibility, and by a hard and distended state of the femoral vein, from Poupert's ligament along the inner portion of the thigh.

The author, after alluding to cases recorded by M. Meckel, Bouillaud, Velpeau, &c. proceeded to speak of those by Dr. Davis.

In Mr. Lawrence's account of the morbid appearances observed in the

first case related by Dr. Davis, no particular mention is made of the condition of the hypogastric veins, nor does it appear that the course of these vessels was traced to their termination in the iliacs. Mr. L. indeed observes, that the uterus and its appendages, and blood-vessels, were healthy; but of the accuracy of this Dr. Lee entertained some doubt.

The condition of these vessels in Dr. Davis's second and third cases, is likewise unnoticed; but in the fourth it is stated "that the left internal iliac was greatly inflamed, and its diameter so much contracted by the morbid thickening of its parietes, that it was rendered almost impervious." The left external iliac contained a coagulum of blood, which did not adhere to the internal membrane; and in the common iliac, adhesion between the coagulum and inner membrane had taken place; thus shewing that these vessels had become inflamed subsequently to the affection of the internal iliac vein*.

Dr. Gooch had an opportunity in 1823 of examining the uterus of a patient who had died of phlegmasia dolens, and he found the uterine sinuses severely inflamed, several of them being plugged up with lymph, and their inner surface coated with a membrane of a red mulberry colour. The state of the hypogastric and iliac veins was not ascertained. To Dr. Locock, who also examined the uterus, Dr. Lee was indebted for this fact.

None of the eminent authors who have now been quoted have made any allusion to phlegmasia dolens commencing in the uterine veins; and M. Velpeau, the latest continental writer on this subject, has given it as his opinion that the affection of the veins is not the primitive disease, but is the consequence of the inflammation and suppuration of the articulations of the pelvis, with which he has observed it to be occasionally combined.

It is due to Mr. Guthrie to mention, that in a paper on inflammation of veins after amputation, published in the *Med. and Physical Journal* for 1826, he suggested the importance of tracing the veins from the common iliac of the affected side down to the uterus, and expressed his suspicion that the disease

* Transactions of a Society for the Improvement of Med. and Chir. Knowledge, vol. II].

* *Med. Chir. Transact.* vol. xii, p. 429.

would be found to originate in that organ.

All the different authors who have treated of phlegmasia dolens describe it as commencing, in the great majority of cases, subsequent to the tenth day after parturition, with symptoms of uterine irritation and constitutional disturbance of a low nervous character, and with pain and swelling in one extremity only. They have assigned various reasons for these remarkable peculiarities in the period and mode of development of the disease, such as pressure of the gravid uterus on the iliac veins during gestation, the change in the distribution of the blood from the sudden removal of this pressure, suppression of the lochial discharge, exposure of the extremity to cold, &c.; all of which, however, taken singly, or combined, are insufficient to account for the phenomena; and the occurrence of the disease after menstruation and abortion proves that the above causes are not necessary for its production*. The facts which have now been stated afford a more satisfactory explanation of these phenomena, and shew that if inflammation be excited in the orifices of the uterine veins, it may spread along these to the iliac and femoral veins, and by the morbid changes induced in them, give rise to all the subsequent symptoms.

With a view of illustrating the subject, the author next adverted to the principal facts relating to uterine phlebitis, of which he considered phlegmasia dolens to be merely one of the remote consequences.

The effects of inflammation in the uterine veins, are the formation of adventitious membranes on their inner surface, and the deposition of coagula of lymph, or of purulent matter, within their cavities. Coagula of the fibrin of the blood, which extended a considerable distance into the uterine veins, are formed in their orifices after every labour, and are the principal means employed by nature for the permanent suppression of uterine hæmorrhage. These may be distinctly perceived for a long period after delivery, and have a different form and colour from the coagula produced by inflammation. In opening the body of a patient four weeks after confinement, Dr. Lee observed distinct

traces of these partially absorbed coagula in the muscular substance of the uterus, at the part where the placenta had adhered.

The inflammation may be limited to the veins, but not unfrequently the muscular tissue of the uterus contiguous to them participates in the inflammation, and becomes of a dark red, or blackish brown colour, and so soft in its consistence as to be readily torn with the fingers. The peritoneal covering may be also affected, and the usual consequences of puerperal peritonitis will then ensue.

The veins which return the blood from the uterus and its appendages may be either wholly or in part inflamed; generally, however (and this is a circumstance in the history of uterine phlebitis deserving attention), the inflammation attacks the spermatic veins, and for the most part the one only on the side of the uterus to which the placenta has been attached; and it may either confine itself to a small portion of the vessel or extend throughout its whole course, from the uterus to the vena cava. The usual consequences of inflammation are then apparent,—viz. injection and condensation of the cellular membrane in which they are embedded; thickening, induration, and contraction of their coats, and the deposition of lymph, mixed with pus and coagula of blood within their cavities.

The same is true with regard to the hypogastric veins, one only being generally affected: but inflammation having once begun, it is liable, as Dr. Lee had before stated, to spread continuously to the veins of the whole uterine system, to those of the ovaria, of the fallopian tubes, and broad ligaments. The vena cava itself does not always escape, the inflammation spreading to it from the iliac or from the spermatic veins. This occurrence seldom takes place to a great extent through the medium of the spermatics, the inflammation terminating abruptly at the opening of the spermatic into it on the right side, or of the renal on the left. If it pursue, as it sometimes does, the direction of the kidneys, the substance of these organs, as well as in the veins, may be involved in the disease.

Uterine phlebitis appears to result from the mechanical injury inflicted by protracted labour, from the force required for the extraction of the pla-

* See Burns's Principles of Midwifery, p. 541. Capuron.

centa in the uterine hæmorrhagy, from retained portions of placenta undergoing decomposition in the uterus, the application of cold, and probably of contagion, and from various unknown causes operating on the uterine system after delivery.

It is, perhaps, impossible to determine, for the most part, the precise period of its invasion, from the total absence of local pain and of other symptoms; but it is probable that it most frequently begins soon after delivery, and remains stationary for a time, around the orifices of the uterine veins, as phlebitis has been observed to do where it occurs after venesection. Of this, however, we can have no certain proof, nor can it be admitted to be a general occurrence, from the rapidity with which the inflammation has been found to attack the uterine, spermatic, and renal veins. In one case, Dr. Lee saw the disease prove fatal on the evening of the fifth day after labour, and, on dissection, all these veins were found to be completely disorganized by inflammation.

It may be stated as the general result of all the observations which have hitherto been made on the subject of uterine phlebitis, that it occurs most frequently from the tenth to the twentieth day after parturition, though it has been observed to commence at an earlier, as well as at a much later period.

Where the veins alone are inflamed, the peritoneal and muscular tissues remaining unaffected, there is often either no pain or only a dull pain, with a sense of weight in the region of the uterus, and no other local symptom by which the disease can be recognized. The uterus, too, may return to its usual reduced volume, or nearly so; and it is only on the accession of the constitutional symptoms which have been previously detailed, that the existence of this insidious and dangerous affection can be determined. If the substance of the uterus be affected, this organ remains above the brim of the pelvis, large, hard, and painful on pressure, as in puerperal peritonitis.

With regard to the lochial discharge, it has sometimes been observed to be foetid and puriform, and at other times in a perfectly natural state.

The constitutional symptoms of uterine phlebitis, and the important alterations produced in the structure of the

brain, lungs, liver, and other internal organs, and also in the synovial, serous, and cellular membranes, are often so peculiar and characteristic, that it is the more remarkable this disease should have been so long overlooked by pathological inquirers. It is true it was stated by others, many years ago, but they pointed out merely the lesion of the uterine veins, without having observed the important constitutional effects to which the disease gives rise.

Recent experience has induced Dr. Lee to believe that uterine phlebitis is of far more frequent occurrence than has yet been suspected; and that to it must be referred many of the fatal disorders of puerperal women which have usually been comprehended under the vague designation of puerperal fever, or peritonitis. Inflammation of the uterus, and its appendages, may be considered as essentially the cause of all the destructive febrile affections which follow parturition; and the various forms they assume, inflammatory, congestive, or typhoid, will probably be found to depend on the serous, muscular, or venous tissues of the uterus being affected.

In order still further to illustrate the observations on uterine phlebitis, Dr. Lee subjoined an account of several examples of the disease, which have recently come under his observation; one of these, in which several striking peculiarities occurred, was published in this Journal, April 25th, 1829.

The first was a case of inflammation of the uterine and right spermatic veins after parturition, with gangrenous inflammation of the lungs and pneumothorax of the right side.

The second, uterine phlebitis with ulceration of the articular cartilages, and purulent effusion within the capsular ligament of the right knee-joint.

The third, inflammation of the uterine veins, with carcinomatous ulceration of the os and cervix uteri.

The fourth, inflammation of the left iliac and femoral veins, with phagedenic ulceration of the uterus.

Allusion was also made to the case of a woman, who died of cancer of the uterus in the wards of La Charité. She had ascites, and infiltration of the inferior extremities. On dissection, the principal veins of the lower extremities were found greatly distended with layers of coagulum, like those of an aneurismal sac, adhering intimately to their inner coats, which were red and thick-

ened. The external iliac, hypogastric, and common iliac veins, and the vena cava inferior, to near the diaphragm, were found in the same condition.

The manner in which cases of cancer of the uterus terminate, varies extremely in different individuals; some surviving many months the destruction of a great part of the body of the uterus, and the adjacent structures; while others die at an early period of the disease merely from a superficial erosion of the mouth or neck of the womb. This difference may depend in some cases on the greater or less degree of susceptibility of the constitution to the local injury; but it seems highly probable, from the facts now related, that death sometimes results from the production of inflammation in the veins of the uterus.

In cancer of the rectum, Mr. Lawrence has observed in one case, inflammation of the iliac veins; and Laennec has stated, "that it is not uncommon to find the veins in the neighbourhood of a cancerous breast filled with pus, either pure or mixed with blood; sometimes fluid, at other times, of the degree of consistence of an atheromatous tumor."

But little discussion ensued on this important and interesting paper, a circumstance to be attributed to the nature of the communication. A few remarks were made by Dr. Bright and Mr. Lawrence, who complimented Dr. Lee on the manner in which he had treated the subject.

THE KING *versus* JOHN CLAPHAM.

Court of King's Bench, Guildhall,
October 24, 1839.

THIS was an indictment charging the defendant that he intended to impose upon the Apothecaries' Company, and to induce them to admit him to the practice of an apothecary, produced to their secretary a paper purporting to be an affidavit, stating falsely that he was of the age of twenty-one years: in consequence of which the Court of Examiners were induced to admit him to an examination.

The *Attorney-General* (with whom was Mr. Follett) stated, that this prosecution was instituted by the Master and Wardens of the Apothecaries' Company, in order, if possible, to put an end to a very mischievous practice which had of late years grown up. The jury were probably aware, that among

several laws which had been made for the better regulation of the practice of apothecaries, was one which had been passed in the fifth year of the late king. The legislature, thinking it not safe to trust the lives of his Majesty's subjects in the hands of young and inexperienced medical practitioners, had passed a law, enacting that no person should be allowed to practise as an apothecary who was under the age of twenty-one years, or had not served a regular apprenticeship of five years. The act required that, before a person should be allowed to practise as an apothecary, he should obtain a license from the Apothecaries' Company, and for that purpose he was to be examined before the Court of Examiners, who were to certify as to his skill and ability. Before he could be admitted to such an examination it must be shewn that he had attained the age of twenty-one years, and had served a five years' apprenticeship. Of late years, these wholesome provisions of the legislature had been eluded, and the Apothecaries' Company had found it necessary to institute several prosecutions against persons who had attempted to impose upon them by false affidavits and forged testimonials. The charge against the young man who was the subject of the present prosecution, was, that he had imposed upon the Court of Examiners by producing an affidavit, purporting to be made by himself, in which he swore that, at the time he applied to be admitted to an examination, he was twenty-one years of age. The discovery of the fraud had been made by mere accident. The attorney of the Apothecaries' Company happened to read in the newspapers an account of a trial at Westminster, in which the present defendant was examined as a witness. He was on that occasion asked whether he was twenty-one years of age, and he replied in the negative. He was then asked how he had obtained his license as an apothecary, and he was obliged to confess that he had imposed on the Apothecaries' Company by making a false representation. This having occurred at a time when other cases of a similar nature had been discovered, the Apothecaries' Company thought it right to make those inquiries respecting the defendant which had led to the present prosecution. The defendant lived at a place called Thorney, in Northamptonshire, where he was born, and where his parents resided. Witnesses would be called who had known him from his infancy, and the register of his baptism would be produced. This document, with his own admission in the Court of King's Bench that he was under the age of twenty-one when he applied to be examined, would clearly establish the fact of his having imposed on the Apothecaries' Company.

Mr. John Watson examined by Mr. Follett.
—I am the secretary to the Court of Ex-

aminers of the Apothecaries' Company. I have been their secretary fourteen years and a half. Their course of practice is to require certain testimonials from persons who apply to be examined. They require evidence of apprenticeship, age, moral character, and education. The practice is, for candidates to leave the testimonials with the beadle at the hall. He deposits them in a bag, of which he keeps the key; and on a certain day he delivers the papers to me for the purpose of examining them. After examining the documents, I make my report to the Court of Examiners. In April, 1828, I received certain papers, purporting to be testimonials on behalf of the defendant, John Clapham. Among them was an affidavit, purporting to be made by him.

The affidavit was put in and read. It purported to be sworn before Mr. Laing, at the police-office, Hatton-Garden, in April, 1828. It described the defendant as a medical student, residing at No. 21, Oxendon-Street, Haymarket, and stated that, to the best of his knowledge and belief, he was twenty-one years of age.

Mr. Watson stated, that it was also required by the Court of Examiners, that candidates should sign a declaration. The defendant had signed such declaration, and therein described himself as of Thorney. He was afterwards examined by the Court of Examiners, on the faith of the testimonials produced, and a certificate was granted.

On cross-examination by Mr. Brougham (who, with Mr. Kelly, appeared for the defendant), the witness stated that it was usual to require a certificate of baptism; but no certificate had been required in this case.

Thomas S. Watson stated, that he knew the defendant, John Clapham, who was the son of William and Sarah Clapham, of Thorney, near Peterborough. Witness had known him since he was a week old. He lives at Thorney, and assists his father in his business of an apothecary.

An examined copy of the baptismal register was put in. It shewed the date of the baptism to be the 22d of August, 1809, and stated the birth to have taken place on the 3d of January, 1808.

Lord Tenterden.—We cannot take this as evidence of the birth: it only shews the time of baptism.

William Oliver (a short-hand writer) produced his notes of the trial of the cause, "*Cooper v. Wakley*," in the Court of King's Bench, on the 12th of December last, and read therefrom part of the defendant's examination. After stating in his examination-in-chief that he was a licentiate of the Apothecaries' Company, and was in practice with his father at Thorney, he stated, in answer to questions by Sir James Scarlett, that he was a pupil of St. George's Hospital,

and obtained a license from the Apothecaries' Company in the spring of that year (1828), on a false representation that he was then twenty-one years of age.

This was the case for the prosecution.

Mr. Brougham admitted that he could make no defence, and said he would reserve those topics which he had to urge in palliation for another place. The Apothecaries' Company, no doubt, did their duty in instituting such prosecutions as these, for the purpose of arresting a practice which had certainly been prevalent for some time past; but his learned friend, the Attorney-General, in eulogizing the object of the legislature, had forgotten that there was a very great hole in the act of parliament, for it allowed chemists and druggists to make up grouts without any certificate of qualification. He felt, however, that he should be wasting time were he to urge in this place any thing in mitigation of the defendant's conduct.

The Jury immediately returned a verdict of *Guilty*.

HOSPITAL REPORTS.

ST. BARTHOLOMEW'S HOSPITAL.

Lithotomy.

[MR. LAWRENCE, a few nights ago, made the following remarks on a case of lithotomy, at the conclusion of his surgical lecture.]

I wish to advert shortly to the case of a patient with stone, on whom I operated last Saturday, for the purpose of illustrating the way in which elderly persons, or rather those of debilitated habit and system, die after serious operations. This patient was 67 years of age, of feeble habit, and in a weak state of health. He had suffered three years from the stone, and had come to town for the purpose of having it removed. This was accordingly done, although the case could not but be regarded at the time as one of an unfavourable description; at all events, it might be looked upon as a chance whether the patient would live or not, and perhaps the unfavourable chance rather preponderated. However, the state of suffering in which a person lives in an affliction of this kind is so intense that I think it better to run the risk, and that is generally the sentiment of the patient himself. He lost, perhaps, about ten ounces of blood during the operation, a quantity which was certainly not very considerable. He was removed to bed, and I gave him two grains of crude opium. It is the practice in some places to administer opium after operations generally, but that is not my practice. In the case, however, of a patient like this, I consider that an opiate may be advantageously employed; so it turned out here, for the patient fell asleep soon after the operation,

and continued so for fourteen hours. When he awoke, he said he felt rather thirsty, and his pulse was found so feeble that it was necessary to give him wine and water. From that period to the time of his death, which happened yesterday evening, he continued gradually sinking. His pulse was generally feeble; his muscles were tremulous and starting; his voice was feeble, and he could only speak in a low whisper. The tongue was rather dry, with a brown streak over the middle. He employed the abdominal muscles in respiration: and there was not a symptom of inflammation going on. The urine passed by the wound, but not in the usual quantity, for in fact his state was such that the usual quantity of urine would not be secreted. In the course of yesterday a swelling took place at the posterior part of the pelvis—that part on which he lay in bed, apparently produced by the state of general debility. On examining the body, (the appearances of which may be summed up shortly), there was no kind of inflammation, nor any serious disease to account for death in any part. The peritoneum was perfectly free from inflammation; there was nothing like inflammation in the bladder, or in the cellular membrane around. All that we could observe was, that there appeared to be rather a deficient quantity of blood: this was observable especially in the right cavity of the heart, in which we usually find a considerable quantity. The kidneys were not in their natural state, but were pale; and the glandular structure was rather firmer than natural. The mucous membrane of the pelvis manifested no increase of vascularity. There was a slight concretion in one kidney, and a little purulent matter in the other.

Thus this person has died, as old persons frequently do, without any organ being materially affected, and without the existence of any visible disease to account for his death.

The following is a short note of the case above alluded to.

James Elprick, a short emaciated man, aged 67, was admitted into Darker's ward on Thursday, October 8, with symptoms of calculus in the bladder, which had existed about three years. It being the wish of Mr. Lawrence and Mr. Earle that the operation of crushing the stone should be had recourse to, the patient was brought into the operating theatre on the Saturday following at the usual hour, when Baron Heurteloup, after a careful examination, pronounced the present one an unfavourable case for the operation of lithotripsy, as the stone was of large size, and the bladder very small. The patient had also a large rupture in each groin, one of which had existed about ten years, the other about two.

17th.—The patient was again placed on the

operating table, when Mr. Lawrence extracted a large calculus by the lateral operation; during which about ten or twelve ounces of blood were lost from the division of the peroneal artery. After the patient had been removed to bed, two grains of crude opium were administered, when he soon dropped off into a sound sleep, which lasted fourteen hours. On waking he complained of slight thirst, but felt quite free from pain. The pulse being feeble, some wine and water was administered. Notwithstanding the free use of brandy and wine, he died last evening, apparently from general weakness, as no reaction whatever had been produced. His pulse continued weak; his muscles tremulous, as if he had no voluntary power over them; his voice became feeble, so that he could only speak in a whisper. His tongue was always rather dry, having a brown streak extending all the way along the middle line.

21st.—At half-past one o'clock to-day, Mr. Lawrence proceeded to examine the body, when no appearance whatever to account for death was observed. There was not the slightest appearance of inflammation in the abdomen, or in the bladder, or seen in the cellular substance surrounding it. The kidneys were rather paler than natural, and in one was found a little calculous matter. Less blood was found in the cavities of the heart, and in the large vessels, than is usually observed.

Our Hospital Reports this week have been *pushed* out, by the length of the Report from the Medico-Chirurgical Society, and by the account of the Trial at the Court of King's Bench.

LITERARY INTELLIGENCE.

Dr. Pring has in the press a work entitled "Sketches of Intellectual and Moral Relations," which, it is expected, will be ready for publication in the course of next month (Nov.)

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

LECTURE VI.

October 12th, 1829.

On Inflammation ;—Recapitulation—Causes.

I SPOKE to you, gentlemen, in my last lecture, of the varieties which the inflammatory process presents, according to the circumstances under which it takes place; and I fear that, in the attempt to conclude the subject within an hour—the period allotted—I may not have explained myself so fully on all points as I could have wished.

It is difficult, perhaps, to give an exact description of all the stages which are included between the first deviation from health and the worst effects that are produced by disease, but I endeavoured to enumerate them as follows. *Irritation*, in respect to internal organs, is evinced simply by an alteration in the functions of the part; and we cannot positively say whether, under certain disturbances, such an actual organic change is produced as to warrant us in calling it inflammation. But, in the external parts, we are often enabled to see recognizable changes of an inflammatory kind, accompanying slight alterations in the functions of the organ. Thus we observe distention in the external vessels of the eye; if it arise from a slight cause this state is transitory, and such as, of course, we should have no means of ascertaining if it took place in an internal organ. In explaining the stages of disease, we should call this state of irritation the first step in the deviation from health. We have besides *congestion*, or what is called determination of blood, a condition which is generally ascertainable

after death, for you can see a preternatural fulness of vessels in the organ: *hæmorrhage*—that is, a breach of some of the vessels of a part, in consequence of which blood is effused, making its appearance externally if it takes place on the surface of a membrane, having an external opening, or in internal parts if there be no external opening; effusion of *serum*, effusion of *lymph*, *suppuration*, *ulceration*, and *gangrene*. I think we must regard these various events only as different modifications of that disturbance which, when it has arisen to a certain degree, constitutes inflammation. We cannot say precisely that all these are simple differences in degree; we cannot, in that respect, compare them to each other, because we find that the difference of texture produces a tendency to one form of change rather than another, without our being able to say that the disease is comparatively more or less severe. *Hæmorrhage*, for example, takes place easily from the surface of a mucous membrane; but not from the surface of a serous membrane. We cannot actually determine whether the disturbance which produces this discharge in a mucous membrane is greater or less than that which produces coagulated lymph in a serous membrane;—if we say they differ in degree, we cannot venture to assert in which stage of its progress one is actually greater than the other, because there is a difference in the nature of the disturbance which we cannot precisely account for.

These are the more immediate effects of inflammation: under the head of remote consequences I have spoken of *induration*, or that kind of thickening and increased hardness in a part which more or less interferes with the functions permanently, and which is opposed to another termination which occasionally takes place—that of preternatural *softening*; a change which is observed especially in the brain. With respect to induration, it exhibits itself in two forms. In the majority of organs, the indu-

ration is of a white kind—that is, the substance that is indurated does not possess a great number of blood-vessels, therefore it is a whitish change in the structure of the part; but in certain organs which possess an abundant supply of vessels, and where there are numerous capillaries, this induration is of a more or less red colour. This is observed in the lungs, liver, and certain other parts; and in the case of the lungs, where it is common, is, by the French, called *hepatization*, because it produces a change in their substance; which, in point of colour, sensibly approximates to that of the liver. I should also have spoken to you, in my last lecture, of the varieties which inflammation presents in the several textures of the body. When you are informed that inflammation is an augmented action of the vessels of a part; when you learn that the seat of inflammation is in the capillaries; when you know, at the same time, that the arrangement of these vessels presents a difference in each organ—you will naturally be prepared to conclude that the inflammatory process will have its peculiar characters in each structure; that there will be something particular that will distinguish the process, in every part in which it occurs.

There are certain leading characters, which we have already pointed out, which are more or less perceptible in all parts of the body; but yet, in each texture and in each organ, there are particular phenomena which distinguish their inflammation from that of any other part.

Suppose we take the membranes, either altogether, or the parts which resemble each other considerably: you find in each division that inflammation exhibits a distinct character. In the mucous membranes, inflammation is characterized by a great distention of the blood-vessels, with which their surface is very largely supplied; and thus a bright scarlet redness is one of the characters of this action in them. Swelling, and increased thickness of the inflamed texture, is another character. An increase in the quantity, and an alteration in the quality of the fluid which these membranes naturally separate from the blood, is a third character; and the fluid so increased in quantity and so changed in the appearance it presents, chiefly characterizes the stages of the disease. Such are the circumstances that particularly mark inflammation of the mucous membranes. If, now, we turn to the serous membranes, we find that the disease there is of a different character. In serous membranes there is no perceptible swelling, nor increased thickness; there is in general no increased redness, or scarcely any that is perceptible. If you fancied that in the case of an inflamed

peritoneum you saw an augmented redness of the surface, you would, perhaps, find that it was produced by a distention of the vessels that are seated beneath it; and if you were to detach the serous membrane from the parts over which it lies, you would probably find no increase in the vessels that actually belonged to it. Increased exhalation on the surface, and a conversion of the fluid subsequently into one that cannot be distinguished from pus—and farther, the deposition on the surface of coagulable lymph; these are circumstances which characterize inflammation of the serous membranes. The coagulated lymph thus deposited becoming subsequently organized, constitutes the material of preternatural adhesions; forms *adventitious membranes*—that is, a new substance covering the surface of the parts. These depositions on the surface of serous membrane give to it, in many instances, the appearance of being increased in bulk; but if you remove the adventitious formation, you find that the original textures are not increased in thickness. Now, as there is a great and essential distinction in the characters and products of inflammation in these two membranes, you scarcely can, by any artificial means, produce in one what takes place in the other. Mr. Hunter tried, by applying powerful external irritants, to produce in the mucous membranes the same effusion of coagulated lymph which occurs in the serous membranes; but he could not succeed. You will immediately foresee, when you reflect on the organs to which the serous and mucous membranes respectively belong, that if the latter were liable to the same abundant deposition of coagulable lymph, and to preternatural adhesion from false membranes, like the former, the functions of the parts would be completely destroyed. Consider the state of the stomach, and other portions of the alimentary canal: those tubes would be blocked up by such depositions. Thus you see why inflammation has one kind of termination and effect in one case, and not in another: at all events, such is the fact. As to the fibrous membranes, in inflammation of the dura mater you do not perceive effusion of lymph, or the secretion of fluid like pus; but there is an interstitial deposition—a thickening of the part.

All the textures of the body, when injured, wounded, or divided, will inflame; but when we speak of the inflammations that arise in the various organs of the body, from *internal causes*, and not from *external injuries*, we find there is a great difference in respect to the tendency and the effect of the diseased action. The cellular membrane is particularly prone to suppuration, and there it takes place very easily;

but the glandular structures of the body are by no means easily brought into this state. In many of them we hardly know an instance in which suppuration takes place. I fancy it has happened to few persons to see an abscess in the kidney or spleen; and in these climates it is rare to see it take place in the liver. The testicle is an external part, and is frequently the seat of inflammation; and yet suppuration in the testicle is very rare. Suppuration is hardly ever seen originating in spontaneous inflammations, or those that arise from internal causes in the substance of the muscles, or in the substance of the tunics of the stomach, or other parts of the alimentary canal. Mortification takes place easily in the cellular membrane; and this is the texture in which this alteration is most frequently observed, and in which it occurs most quickly. Mortification takes place frequently in the external parts generally, but it is a very rare occurrence in the internal organs.

I now come to speak of the *causes of inflammation*; and these include all circumstances that can act on the human body.

I have already mentioned that the great majority of diseases are inflammatory; therefore you will be prepared to find that the various causes which act on the human frame are in general capable of exciting inflammation. In the first place, inflammation is excited by all kind of injuries, whether *mechanical*, *chemical*, or of a *mixed* nature. Inflammation is the consequence of wounds, whether they be incised, lacerated, or contused: it is consequent, therefore, upon surgical operations. It is produced by pressure on the body, whether it be exerted externally or take place from internal causes, such as distention from the growth of tumors, or aneurism. Inflammation is produced by the application of heat; by the application of strong acids or pure alkalis; by various metallic salts, and by numerous acrid substances, whether they belong to the class of chemical agents, or be of animal or vegetable origin. Under the class of animal substances we may include what are called morbid poisons. Active inflammation is produced by the bites and stings of particular insects; by those of venomous serpents; and by those of rabid animals—a description of injury that may be called of the morbid kind. Inflammation is produced by the application to the body of cold and moisture, and by various other atmospheric changes, the nature of which we cannot, in all instances, exactly appreciate: though we find that such influences are capable of producing this action in the parts with which they come in contact. Under certain circumstances, cold air, particularly if it is combined with

moisture, will produce inflammation of the eye. The same kind of cause, immediately applied to the mucous membranes of the nose, the throat, the trachea, and the air passages of the lungs, will cause inflammation of those parts. Again, the application of cold and moisture to the skin—the external part of the body—is capable of producing inflammation in some internal parts, or in some one remote from the seat of direct application. Thus, if a person gets wet feet, he may thereby have an attack of catarrh, of sore throat, or of rheumatism. Cold and moisture, and various other atmospheric conditions, are capable of inflaming *directly* the parts to which they are applied, or *indirectly* the internal and comparatively remote parts of the body. Again, the organs may become inflamed in consequence of excessive exertion in the execution of their natural functions: thus, if the eye be employed beyond a certain extent, if it be exerted to a great degree in the observation of minute objects, if it be used for a great number of hours, inflammation may be produced in it. Excessive mental exertion will cause a disorder in the head, in the same way that the stomach, or other parts of the alimentary canal, the lungs, or the various other organs, may be the immediate seat of inflammation in consequence of unnatural exertion in the execution of their ordinary functions.

With respect to the causes of inflammation that I have now mentioned, they admit of being divided into two classes. Some of them, such as external injuries, or the application of certain chemical substances or morbid animal poisons, will produce inflammation in some degree; it may be more, or it may be less—but inflammation in some degree is the necessary result of their application. Suppose we take the case of *surgical operations*. If a surgical operation be performed on a person who is carefully prepared for it, and in other respects healthy, a slight degree only of inflammation will be consequent upon it; but if the individual should be unhealthy at the time of the operation, or if no means be taken to place him under circumstances favourable to its performance, considerable inflammation will be produced. If you extract a cataract from an individual who is in an healthy state of body, and whom you have carefully prepared for it, perhaps you will have hardly any perceptible inflammation; but if the operation is performed upon a person of gross habit, it is very probable that active inflammation of the iris will result. If an operation is performed on an individual in whom plethora is manifest, without means being taken to prepare him for it, such inflammation may be produced as shall entirely frustrate our object.

With respect to other causes—that is, the application of cold and moisture, or the excessive exertion of the organ itself—they do not act invariably so as to produce inflammation, but they do so under certain circumstances. A considerable number of individuals may be exposed to the action of either cause, and in many of them no kind of apparent result takes place—but still a certain proportion of them suffer from it. For instance: you may have a considerable number of persons exposed to cold, wind, rain, or snow, and the greater number of these shall not suffer any injurious consequences at all; but, perhaps, one out of the number may have a sore-throat produced, another may have an attack of catarrh, a third of rheumatism. A number of persons may sit down to a feast, and perhaps only one individual out of the whole will experience an attack of apoplexy, or palsy. A person who is in good health receives a slight blow on the foot, or a slight twist of the ankle, and, with the exception of the temporary inconvenience that is produced, he experiences no further injury; but if either of these circumstances happen to a person of gross habit, he, perhaps, has an attack of the gout brought on in the part.

Thus we have to consider, not merely the causes that are applied, but also the state of the individual to whom the application is made; and this brings us back to the distinction that I have already had occasion to mention, between the direct, immediate, or exciting causes of inflammation, and those which are remote or predisposing. The exciting causes, in many cases, will not produce disease unless the individual has been prepared for their action by the influence which is produced by the predisposing causes.

Now, under the head of remote or predisposing causes of inflammation, or disease of any kind, we must enumerate, in the first instance, the natural peculiarity of the organs which belong to the individual.

All mankind are not constructed alike. There are differences in their organs; there are consequent differences in the manner in which the functions are executed by those organs; and hence a state of health, which is merely a general expression of the combined result of the actions of all the organs, will present a variety in each individual. If we look throughout the whole of the works of nature, we see that it appears to be her object every where to produce variety. Nature, if we may personify her, seems to have nothing like what we may call the *quakerish* taste; she seems not to delight in a uniformity of colour or shape; she does not appear to have any idea of cutting out all mankind by one pattern. There are, in fact, numerous varieties in respect to organization and to function: in the first place, varieties which are common

to a considerable number of individuals; which therefore admit of being arranged and classed by names; and which varieties constitute the difference which physiologists have denominated *temperament*, or constitution. It is the predominancy of particular actions or sympathies of the organs, in certain individuals, that constitute the sanguineous, the nervous, the lymphatic, and the chylopoietic temperaments. In the first, the circulating system; in the second, the nervous system; in the third, the absorbent; and in the fourth, the alimentary or digestive system, seems to be predominant, or to bear the leading character in the organization. These differences in the temperament, or constitution, have been recognized from the remotest times, and no doubt they are found in nature.

There are, then, certain *general* differences which are common to a number of individuals; and there are certain *peculiar* differences which belong to each part and person; these last are called *idiosyncracies*. This is a Greek term, which means peculiar mixture, as if it denoted the particular proportions in which the various organic elements are combined in each individual. Now we find, in point of fact, that there is something peculiar in the constitution and bodily character of every one. We see this particularly marked by the effects which certain external agents produce on each individual. We observe that particular medicines, or particular kinds of food, produce certain effects on some individuals that they do not on others. There are some persons in whom it is difficult to affect the system with mercury; there are others, in whom a blue pill, or a small dose of calomel, will produce violent salivation; and there are a variety of other differences of the same kind.

Another law of nature is, that organized beings produce, by generation, new beings like themselves, otherwise species and races would not be preserved: and this law, by which the progeny partakes of the character of the parents that give birth to it, extends to the diversities I have just mentioned—the difference of temperament, and sometimes the individual difference;—and thus it happens that the temperament and disposition to certain diseases, are inherited and run, in different families, just like particular forms of the features.

We come in the next place, in considering the circumstances which give a predisposition to certain diseases, to consider what are called *morbid* dispositions. The different temperaments are, as it were, *natural* dispositions; but there are *morbid* dispositions, and these approach nearer to a state of disease than the diversities that I have just mentioned, yet it would not be very easy to draw a line of distinction between them and those differences which constitute the varieties of temperament. As examples

of morbid disposition, I may mention scrofula, gout, and rheumatism. These, in some persons, depend merely on the original nature of the constitution, which is termed hereditary; but, in others, they consist in certain states of the frame which may be produced by external agents, in individuals that are supposed to be born healthy. Morbid dispositions are, therefore, *hereditary* or *acquired*. To such dispositions the technical name of *diathesis* is sometimes applied: thus we have the scrofulous, gouty, and rheumatic diatheses.

Age and sex, in some instances, give a particular form to disease; and climate and situation have certainly a marked influence upon it. Great atmospheric temperature disposes to inflammatory affections, particularly of the skin: thus, erysipelas is of common occurrence, and it is serious in its nature in hot countries. The liver is particularly liable to be affected by a high degree of atmospheric temperature, and abscesses, as the consequence of inflammation, are common occurrences in those parts of the world where the climate is hot;—nothing is more common than those affections in Europeans who visit the East and West Indies. The yellow fever, a dreadful scourge in the latter country, manifestly owes its origin to the effect of a high degree of heat on the system; in fact, the degree to which the liver participates is evinced by the name *yellow fever*, a name derived from the tint of the skin consequent on the biliary secretion.

I have thus far considered inflammation as the result of causes acting solely on the parts that are the seat of such disorder; that is, I have considered what we may call incidental inflammation—inflammation that occurs exclusively from causes that are immediately applied to the organs. But, in many instances, we cannot trace the application of any cause to the organ that is the seat of disease. This happens in a great number of internal inflammations, and also in several external ones, and these cases are called *spontaneous* inflammation. We do not mean to assert that inflammation actually occurs of itself; we do not mean to say that the effect of inflammation takes place without an adequate cause; we only denote by this term that the effect is produced without any ascertainable cause. Thus we frequently observe in children that inflammation of the brain takes place, leading to an effusion of water in the ventricles, which is called *hydrocephalus*. We see inflammation of the pia mater supervening, and producing various affections of the head, and frequently mental aberration. We may have inflammation of the liver or other viscera, erysipelas, inflammation of the synovial membranes, or joints generally. Thus you may have inflammatory affections either of the internal or external or-

gans, arising where you cannot actually trace the application to the organ of any cause capable of inducing disease; and hence we establish the head or division of *spontaneous* inflammation in contradistinction to that of *accidental* inflammation, which includes those where you can observe a cause immediately applied to the part.

Now, although we cannot in many of these cases trace the application of any local cause to the seat of disease, we can often discern the remote or predisposing causes which we may consider to have an influence in determining its occurrence, and we find that these predisposing circumstances are also equally capable of leading to the occurrence of incidental inflammation, but do not necessarily produce it, except under certain circumstances.

The most powerful and most general of the remote causes of inflammation, whether we consider the spontaneous or incidental form of the disease, undoubtedly is what is understood, in common language, by fulness of habit, or what is technically called, general plethora of the system; that is, an unhealthy condition produced by taking into the body an excessive quantity of new materials, in consequence of indulgence in the pleasures of the table, either by eating or drinking too freely. The natural supply of the frame requires that a certain quantity of new material should be introduced into it. Persons, however, are in the habit of consuming, perhaps, two or three times the quantity that the natural wants of the economy require, and hence arises a state of repletion. The digestive organs are overloaded, and an unnatural state of fulness occurs in the sanguiferous system which receives the aliment prepared by the digestive organs. In point of diet, most persons err alike in quantity and quality, and both of these seem to take place chiefly in two articles, that is, in animal food and in fermented liquors. It is, perhaps, difficult to determine what is the *minimum* of supply which will keep the body in a healthy state; but we have facts from which we conclude that a much smaller quantity is sufficient for the purpose than persons are ordinarily in the habit of taking. There is a very celebrated example, that has often been quoted, and many times in this theatre,—that of a Venetian nobleman, named Cornaro, a person who, having been in the habit of indulging in the way alluded to, when he arrived at the age of forty fell into a very bad state of health. Having invoked the aid of physicians in vain, he took his case into his own hands, and determined to try what he could do by abstinence. He found it relieve him, and, persevering in a rigid system of temperance, he in a comparatively short time, got rid of all the complaints that he had been previously troubled with. He steadily pursued this plan, and

he attained to the age of upwards of 100 years, leading a very active life, and in the full enjoyment of all his powers, bodily and mental, filling an important office in the state, and being, in fact, a character of considerable influence in Venice. He has left behind him a small book, in which he mentions the circumstance that I have now recited. He states that he enjoyed his bodily and mental vigour on a diet which included only twelve ounces of solid food, and fourteen ounces of liquid, *per diem*: that would be four ounces of solid food taken three times a-day. He states that this system of abstinence was so necessary to his health, that when he exceeded his usual allowance, so as to take fourteen ounces of food, instead of twelve, he became hot and feverish, and felt such unpleasant effects, as shewed him the necessity of going back to his former quantity.

I was very well acquainted with a lady who enjoyed remarkable health through a long life. She was the mother of a numerous family, and was always robust and hearty; capable of taking exercise and enjoying rest, although she lived a very temperate life, never allowing herself under any circumstance more than a single glass of wine, and taking about one half the quantity of food that persons ordinarily do. She was occasionally the subject of slight attacks of an inflammatory nature, sometimes of erysipelas in the face. At rather an advanced period of life she had an attack of determination of blood to the head, which required an active system of abstinence for a considerable time. This proves that the quantity of animal food and fermented liquor in which people commonly indulge, and which they suppose is necessary to health, is not so, as may be shown by a variety of facts. I was myself acquainted with a lady who, from a kind of whim, began to restrict herself to vegetable diet. She was in good health, and it was not at all necessary for her to give up her ordinary habits; but she took a fancy to live upon vegetables and distilled water, and I believe she took no kind of aliment beside, except milk, for several years. I never knew a lady who possessed more considerable bodily powers than she did: she made nothing of a walk of ten miles, and *could* walk twenty; though she was a slight little woman. She bore two or three children, and suckled them for the space of twelve months, during which time she took only what I have mentioned—vegetables and fruit to eat, and distilled water to drink, taking nothing stronger than tea, or tea mixed with milk; yet they were fine healthy children.

Now in London we have opportunities of observing the effect of habits directly the reverse of these. The persons who follow a laborious occupation in this metropolis—the porters, coal-heavers, draymen, and a

variety of others, eat and drink most unmercifully. A great number of them pass through this hospital, so that we have opportunities of ascertaining their habits, and of seeing the effects they produce. As to two or three pots of porter, that is quite a moderate quantity. You would hardly believe that many of these persons go to the extent of eight, ten, or twelve quarts of porter in a day, filling up the interstices with glasses of gin; and take a meal of strong animal food that would be quite surprising. Now these are the description of individuals that are really, by their natural constitution, formed for strength, and for long life. They are the strongest and most hearty men that come from the country, and who, if they lived carefully, might all of them reach old age, with perfect possession of their bodily and mental powers; but they very seldom arrive at all near it. We see a great many of them here in consequence of their habits of life—that is, in consequence of their state of repletion. They are the subjects of inflammation of the internal organs; inflammation of the liver, of the stomach, of the lungs, and of the heart; they go on till they lay the foundation of organic changes; and thus most of these men, if not all of them, are either cut off in consequence of some accidental injury or violence, which speedily leads to the most severe inflammation; or they die of dropsy before the age of 50.

I remember being called to a fine stout young fellow, one of Whitbread's draymen, who was under 30, and quite a picture as to symmetry. He had merely scratched his leg against the iron hoop of a butt; he did not think much of the accident, and went about his occupation as usual; his leg became painful, and this mere graze of the skin soon began to be troublesome, and within 48 hours of the time he met with the accident I saw him. At that time the whole of the leg and thigh was swelled, livid, black, and blue, up to the body, merely from the occurrence of a slight accident. Now you will easily understand that the effects which are produced by any erroneous system of diet must be very considerable, for the causes of disease are here applied constantly, and persons are subjected to their action day after day, year after year. When you make inquiry into a person's habits of life, he tells you that he is temperate—that he only takes three or four glasses of wine a day; and three or four glasses look like a trifling quantity. But you must multiply this by 365, and then you see the enormous quantity of alcohol that goes into his stomach in the course of a year. This state of unnatural repletion, in the first instance, seems to be attended with rather an increase of health and strength, and the person feels robust and well; all the organs act power-

tally, and a high state of health appears to be produced. But after a certain length of time a condition of body results that approaches to disease; there is a fulness of pulse—a preternatural fulness; there is a disposition to heat and thirst on any exertion; in fact, a state is produced that closely borders on disease; and though you cannot actually say that the individual is diseased, yet he is on the very borders of it: a very slight impulse destroys the balance, and he passes into a state of *plethora*. In this case the accuracy of the expression has been doubted, and it has been questioned whether there is, in fact, real plethora: it is difficult to determine whether it is so or not. In fact, we do not know what the natural, regular, or normal quantity of blood in a particular individual is—we cannot say how much blood there is in a person naturally; therefore we want terms of comparison. You will find in many that there is an unnatural fulness and strength of pulse; and that there is frequently heat of the body, or at least this is produced by slight exertion. We often find, when we bleed these individuals, that the blood presents the appearance which characterises that drawn from those actually labouring under inflammation. Such persons are in a state very similar to that of females in whom the catamenia have been suspended, where we see flushing of the countenance, pain in the head, and a state of fulness in the vessels of various parts. The same symptoms are seen in patients in whom large ulcerations have been rapidly healed. For my own part I am inclined to believe that there is an unnatural quantity of blood in such persons, and that the expression of plethora is literally correct.

I remember a person who came under my care with a cataract, for the purpose of undergoing the operation. He was a man about forty years of age. When I asked him how he was, he replied, "very well—in perfect health;" but he had an enormous head, with a particularly large face, which was of a sort of deep-brownish red, or livid colour. In fact, the appearances were such as to indicate a state of the capillary circulation that I did not like to see in an individual who was to undergo an operation of this kind. This led me to investigate into his previous mode of living: I found that he had been in the habit of taking an inordinate quantity of animal food, and an equal proportion of fermented liquors. When I came to examine his pulse, I found that it was full, strong, and hard, and there were other circumstances with regard to his tongue and digestive organs which, although he said they were in a perfectly healthy state, proved to me that it was far otherwise; and I felt certain that if I performed the operation, inflammation of a destructive kind would be the unavoidable result. I did not operate for ten days, or

perhaps a fortnight, from the period of seeing him, and in the course of that time I took from him 120 ounces of blood; nor did I think it safe to operate until I had done so. Now, I conceive, that this was a larger quantity than I could have taken with advantage, had there not been more in his veins than natural. With this depletion were combined the daily use of purgatives, and restriction from all animal food and fermented liquor, his diet being confined to gruel and broth. At the end of the time he was another man to what he had been at the commencement: thus I brought him to the point at which I thought the operation could be safely performed, and it so turned out; in fact, I never saw one succeed more completely.

At our next meeting I shall proceed to consider the forms of inflammation which are produced sympathetically.

CLINICAL LECTURE

UPON

CANCER OF THE MAMMA,

BY CHARLES BELL, Esq.

Professor of Surgery in the University of London,
and Surgeon of the Middlesex Hospital.

GENTLEMEN,

ON the subject of cancer, I may preserve something more of system than belongs to clinical lectures, at the same time that you may reap all the advantages of this mode of teaching. The number and diversity of cases now in the hospital, enable us to select what subject we choose for discussion. Besides the different stages of cancer of the mamma that we may see in the ward set apart for that disease, we have cancer of the labium and os externum; we have cases of cancer of the uterus; we have that disease which is called cancer of the lip; we have a disease of a different kind destroying the nose—in another, the whole face is carried away; what is more uncommon, we have cancer in the hand, to be operated on the moment the person will consent,—and we have another instance of the same disease in the hand, in a patient just admitted. I must notice also a patient just gone out, who had a cancer of the penis, which I thought was not a proper case for operation. I last night put into

your hands a specimen of the scirrhus contracted rectum, which truly is a cancerous disease, from a poor woman whose sufferings you witnessed in the latter stage of the complaint. These are surely sufficient to convince you of the necessity of attending to this class of diseases, since you could not thus see in one view so many of them, unless they were of very frequent occurrence. I shall not say a word to move your compassion, and in that way to draw your attention, since you daily accompany me through this scene of misery, and the newness of the painful impressions must excite in you—feelings which are almost worn out in me by repetition. It is to the diseases of the mamma now in the hospital that I shall first direct your attention.

Elizabeth Haggard, in Handel's ward, 30 years of age, complains of pain seated in the left mamma. This is a case to which I must demand your attention, lest hereafter, through ignorance, you should place yourselves in circumstances which may affect, not only your professional reputation, but your character for truth. You observe the countenance of this young woman, young in respect to the individuals with whom we have to contrast her; there is here obviously ill health; and, although the breast presents no mark of disease, I believe that she has grounds for her complaints. In short, it is an instance of the sympathetic pain in the breast, occurring when there is no real disease there. These pains in the breast have two sources. The first arise in consequence of change in the womb—of uterine irritation. You recognise them, if depending on the effort of menstruation, by their periodical return, and by swelling and tenderness of the mammae accompanying them. But internal complaints are another source of pain in the mammae; such as disordered digestion; disease of the lungs; and even, as I could prove to you, disease of the heart. Sometimes these pains affect the mammae, shoulder, and elbow, and then the intelligent practitioner recognizes them as being sympathetic. But when they are concentrated in one of the mammae, he is apt to believe that there is actual disease there; and I have had instances in private practice during the present season, where the patients have placed my fin-

ger upon a gibbosity of the cartilages of the ribs, conceiving that this was a tumor of the breast, and they have referred all their sufferings to that. It is now some years ago since a young married lady consulted me; and whilst I undid a roller of eleven yards in length, which was bound round her chest and her arm, I expected at least some abscess or ulcer; but the nipple was prominent, the breast was full and natural, and had not even a *kernel* in it. "What then, madam," said I, "tempted you to undergo this restraint?" She said she had been told by her medical attendant that there was a latent disposition to cancer in her breast: "And you believed him?" "Not altogether from what he said," she answered, "but because of the pain which I feel in it." It was one of these cases of sympathetic pain. This instance occurred during that short period when the regular part of the profession was assailed with the assertion, to which all good-natured people were disposed to assent—that firm compression would cure cancer. The same notion seems now to be entertained in Paris. I have within these five days had a patient direct from Paris, where this system of bandaging had been employed. As I undid the bandaging, and drew the roller towards me, the lady turned round and round so long, that I thought she must at length acquire the spinning motion of a French top. There was no disease in this lady's breast, but there *had been*.

But we must not dismiss this subject of rolling with ridicule. You know its importance in abscess, sinus, and ulcer. Out of any dozen common surgical patients now in the hospital, with ulcer of the lip, or in the ankle, or sinus in the groin, &c. ten of these are profiting by rest and bandage. It is always possible by compression to exhibit in a case of neglected cancerous mamma a remarkable seeming advantage; and actually, in many cases, to do great good. But we shall return to this subject. Let me just remind you that when there is pain in the mamma, you first direct your attention to the condition of menstruation, and secondly, to the state of digestion, or complaints in the chest. This young woman was dismissed with a pill of rhubarb, ipecacuanha, and a little of the blue pill; and she has a powder of columba root, magnesia, and some aromatic; with an anodyne liniment,

which last is yielding to her prejudices rather than strictly conforming to the views which I have just given you.

But before leaving this subject, I shall give you an instance of the wide extent of survey, if I might say so, which you must make in the practice of your profession. I went to see a lady, whose family had grown up, and whom I found very much alarmed by a pain in the mamma. I satisfied myself that there was no actual disease there; but finding her muffled up about the throat, and breathing with a wheezing noise, I entreated to be informed what was the matter with her throat. She then showed me, which she had not intended to do, a brouchocele of very formidable dimensions. I found that it tightened her breathing very much; that she suffered in the night, and was obliged to sit up in bed; and that it was at that time principally she felt alarm from pain in the mamma. Here then you have a disease of the thyroid gland, disturbing the action of the lungs, and that again producing pain externally in the chest, and referable to the mamma.

Mary White, æt. 57. In the hurry of the receiving-room on a Tuesday, this woman was taken into the hospital for extirpation of the mamma; and now you will please to follow the reasons expressed, on consultation, against the operation in this case. There is a scirrhous tumor occupying the mamma, and the nipple is slightly drawn in. These appearances, in addition to the woman's age, are decisive as to the character of the disease; and our duty would be to extirpate the whole breast, were this all: but, on examining the axilla, there is a knot of glands there. When you find this to be the case, your business is, in the next place, to consider whether such tumefaction of the glands has arisen from any thing in the practice of the surgeon, or if it has come on in the progress of the disease. You do not find, in this case, that there has been any application of leeches, blisters, or rubefacients, such as sometimes cause irritation and swelling of the lymphatic glands in the axilla: the inference therefore is, that these have come in consequence of the disease of the mamma itself. Observing these swellings, the next step in the consultation was, to inquire if the disease had gone further; for if it had not, the consultants might still have determined that the extirpation of the

mamma should be performed, and the glands of the axilla be taken out. But you perceive that it has proceeded further; for as soon as the finger is placed above the middle of the clavicle, we feel commencing disease in the glands there. Lastly, on examining the left breast, there is a suspicious hardness in it. The question, therefore, is decided: the *extirpation* of the disease in this woman is a thing impossible. But there is a question of extreme difficulty to be determined—"Ought we to operate when we cannot extirpate the disease?"

To comprehend this question, reflect upon the condition of Mrs. —, who occasionally comes to us as an out-patient. She was in the hospital last Thursday. It is now six years since I operated upon this woman. The case was considered unfavourable: it was the true carcinoma mammæ, and the glands in the axilla were suspected to have taken on them the disease. The wound healed kindly and rapidly; and the case went on very well till about nine months after the operation, when she shewed me the eschar, with a hardness commencing on the upper edge. This yielded to a liniment of the tincture of iodine, and the eschar became smooth; but next year, a tumor began to shew itself in the axilla. If we can say that its progress was retarded by the application of the same remedy, it is all that we can boast of. It is even now a small tumor, and is certainly not the cause either of her ill looks or of her distress in breathing. Her condition now is desperate; she is pale and emaciated, and cannot lay her head down in bed. She is in the last stage of the complaint, with, I fear, effusion into the chest.

It will illustrate this subject if you turn to the report of the dissection of Mrs. J. This woman had also been operated on; and, if we revert to the case-book, we shall see with remarkable success; but she returned upon us with tubercles near the cicatrix, and conscious of her situation; in a few days she died. On examining the body there was effusion in both cavities of the chest, and various cancerous tubercles in the serous covering of the lungs.

Now, gentlemen, these are not cases to win the public attention and exalt the surgeon, but they convey to you the simple truth. Observe, I speak

now of the proper carcinoma mammae, the small hard tumor of the breast, with retracted nipple: this disease we cannot extirpate. We are brought back, then, to our question,—Ought we to operate even although we cannot eradicate the disease? or rather I should express it, *Ought we to operate where there is no possibility of eradicating the complaint, but where we secure a certain advantage by removing a mass of external disease, which is the great source of misery?*

To understand the extent of this advantage, from merely taking away the breast, although the disposition, or even the actual disease, remains internally, look to the condition of Mrs. Malony. She is a sensible woman, and bears up wonderfully against her misfortune. I shall by-and-by state to you the peculiarities of her case, but her present condition is enough for my argument just now. There is an immense chasm in the breast, discharging plentifully, and subject to occasional increase of pain. The discharge and sloughing are offensive to her own nostrils, as you may see by the scent-bottle in her hand. Now, only conceive such a patient in the midst of a private family.—Not to speak of the sufferings of relatives, but only of the patient's, are not her's greatly increased by the pain she gives to others? Here, then, we see the advantages of extirpation; that, although the disease be only checked in its progress on the constitution, yet, by the removal of the external disease, we save our patient from that state of aggravated suffering—the offensive sore—the continued necessity of surgical attendance; and above all, we save her from that mental suffering which is the necessary consequence of a female knowing herself to be offensive to her kindest friends and relatives; and the reflection that, in dying, she leaves an impression so painful as to excite disgust in her friends.

This patient is 48 years of age; and she has now been in the hospital for more than a year. It is about four years since she first perceived a small lump in her right breast, but this was not attended with any uneasiness for some time. In the course of two years, however, it increased in size, became greatly larger than the natural breast, and at length burst, giving vent to a foul sanious discharge. When she

came to the hospital the tumor occupied nearly the entire space from her shoulder to the pit of the stomach: it was elevated, with lobules which were of a purplish blue colour; it had a large chasm in the centre; the edges were everted and again coiled in, and the discharge offensive. The tumor, at one time, was reduced in size in a remarkable manner, its deep purple colour was gone, and the edges of the cavity appeared to be closing, as if they were about to unite: but this condition lasted only for a short period; the tumor speedily developed itself again; and it has continued for some months, with occasional variations, of the same dimensions which you now see.

As I have gone round the ward I have put the questions to this woman in a form to be intelligible to you, and you have heard what her own experience has dictated. The swelling is great, the discharge very abundant, and the disposition to slough has been shewn on some of our visits; whilst on the following she will express herself as much better, relieved of her pain, and we find the tumefaction and inflammation have subsided. It is our business to understand this. The source of this occasional distress must be a principal reason of the continuance of the disease. You have heard her own narration. She is not past the age of menstruation, and the period of the return of the catamenia is that of her most aggravated suffering. If, therefore, we are to attempt to prevent these occasional attacks, we must watch for the time of the return of the menses, and anticipate them by leeches to the hæmorrhoidal vessels, tepid and anodyne injections to the vagina, by the hip-bath, and the union of camphor and opium in pill or as a draught. In short, suppose that I have repeated all that Mr. Abernethy could say on the necessity of attending to the operations of the stomach; and I would add, as the next best thing, attention to the uterine system.

I shall here give you a rapid sketch of the proofs of sympathy between the uterus and the mammae, for indeed it is a matter of consequence for you to attend to this; and were I disposed to be critical, I might say that this subject has been strangely neglected in publications upon this part of practice. You will observe that the first appearance of the menses is attended with uneasiness

and swelling of the breasts; and that on each return of the period, there is the same sympathy shown in the tenderness of the mammæ. Upon conception too, in the state of gestation, and on delivery, there are the most decided changes taking place in the mammæ, in connexion with the womb; and when the uterine system is about to suffer that final change which occurs in the climacteric period of life, the breasts suffer as in all the other changes to which the uterus is subject. In a delicate girl, before puberty, you see the constitution holding out pretty well; but when the uterine change is about to produce that influence both on body and mind which characterises the sex, we often see that the constitution suffers a severe revolution: paleness, languor, and hysterical irritability, are succeeded by pains in the side, short cough, morning expectoration, and consumption. At the cessation of menstruation, a disturbance not less remarkable is exhibited: the plump matronly appearance of the patient is changed for a look of ill health, with sallowness and thinness; she complains of pains in the loins and limbs, like rheumatism; and when an investigation is made into her condition, you find that menstruation has been interrupted—that it has returned after a prolonged interval, not in a kindly manner, but, on the contrary, with pain, difficulty, and unusual discharge, and with actual clots. In this manner the periods have become irregular, and the returns attended with violent symptoms. In the meantime the mammæ are swollen up: on their subsiding, a small kernel is felt, deep in the gland, and this does not subside, but remaining dormant for a time, waits, as it were, for an additional excitement from the same cause to develop itself. We might look to the records of the cases in the hospital, and we should find, that when a young woman, from 18 to 25, has such tumors forming in the mammæ, they partake of the disposition that prevails in the constitution—they are strumous; but when they occur from the causes assigned in a woman from 39 to 50, they are more particularly alarming, because it is the period of life in which a glandular structure, being deranged, is apt to run into carcinoma.

[To be continued.]

ON THE FUNCTIONS
OF THE
LABYRINTH OF THE EAR.

By J. SWAN, Esq.

(For the London Medical Gazette.)

In a preceding paper I stated that hearing in the mammalia was produced both through an impulse given to the labyrinth by the ossicula, and a modified one to the membrane covering the finistra rotunda; so that particular sounds were heard through one of these parts, and not through the other, as I could not conceive that the membrane of the fenestra rotunda existed only for modifying the undulations conveyed through the labyrinth from the ossicula.

If the fenestra rotunda in the mammalia alone be examined, it may be concluded that it exists almost entirely for this purpose; but as the different formation of the labyrinth of birds may appear to invalidate this opinion, I will endeavour to give such an explanation as may tend to reconcile the seeming contradiction offered by this variation.

In birds, the cochlea is not formed as in the mammalia, with the fine internal texture of the lamina spiralis; but is a cavity containing a pulp or thick membrane, on which the auditory nerve is spread. The fenestra rotunda opens into the vestibule, and communicates indirectly with the cochlea by a small aperture, which indeed rather leads to the vestibule than the fenestra rotunda. The slender bone attached to the membrana tympani is observed to pass into a canal, which leads to its insertion at the fenestra ovalis, and the entrance to this seems ill calculated for receiving undulations from the different parts of the tympanum, and conveying them to the fenestra rotunda.

If the fenestra rotunda in birds does not communicate with the cochlea in the same manner, and the cochlea be not divided into two scalæ as in the mammalia, I presume it may be concluded that the scala tympani in the mammalia is formed principally for receiving such impressions from sound as do not act on the fenestra ovalis through the ossicula; for in birds the situation of the fenestra rotunda precludes this action, except in a very limited degree, and must, therefore, exist in them for

modifying the impulse given to the membranous structure of the labyrinth by the slender bone; it may, indeed, convey some undulations from the membrana tympani to the vestibule, in the same manner it does to the cochlea in the mammalia, but, as I have before stated, its situation is unfavourable for this office.

When an impulse is given by the stapes to the membrane covering the fenestra ovalis of the mammalia, can that imparted at the same time to the membrane of the fenestra rotunda tend to repel the stapes, and prevent such a degree of action on the membranous structure of the vestibule as would take place provided no such opening existed? The two distinct scalæ make this somewhat doubtful, as one of them almost entirely communicates with the fenestra rotunda, and the other with the vestibule; the undulations imparted by the membrana tympani to that of the fenestra rotunda may, nevertheless, in some measure answer this purpose, and particularly as the two scalæ communicate at the apex, and are partly divided by membrane. If the membranous structure of the labyrinth were inclosed entirely by bone, it would not receive the impressions or undulations from the stapes with the same nicety it does by the assistance of the fenestra rotunda. The fenestra rotunda in the mammalia varies very much in size, and in some animals is larger than the fenestra ovalis; and this precludes the opinion that it exists merely for counterbalancing the impulse conveyed by the stapes.

Many further inquiries remain to be made respecting the precise uses of the curious configuration of the labyrinth; but it will be previously necessary to take some notice of the functions of the auditory nerve.

When an impulse is communicated from the stapes to the nerves in the labyrinth, is it given to that portion spread on the membranous structure of the cochlea, as well as that of the vestibule and semicircular canals, so that every part of the auditory nerve shall receive an impression from the same sound? I believe every part of the membranous structure does not receive an impulse from every sound, and therefore an impression is not made on the whole nerve.

Supposing an impulse to be given by the undulations to all the nerve con-

tained in the labyrinth, is one part of it capable of receiving only one note or sound, another portion a second, and so on? If this were the case, the most minute divisions of it must have separate properties inherent in them; and I do not believe that the different parts of it are themselves capable of producing these varied effects. Then if an impression be made on the membranous structure of the labyrinth by the stapes, does one termination of a semicircular canal hear A, another B, &c.? and would the part hearing A not hear B, and B A, and so on. I presume the nerve is capable of appreciating the undulations conveyed to the membranous structure of the labyrinth, according to the power given by the form and extent of the cavities, including each of its respective portions. The labyrinth in man might have been more extensive, as it is in some animals, but then it might not have answered the purposes most conducive to his comfort and convenience; he might have heard fainter or more distant sounds than his ear can now appreciate, but he could not then have felt with the same delight either the powers of the human voice or music.

Hearing could not have been produced without the mechanism of the labyrinth, for had the auditory nerve been distributed on a flat portion of membrane, or any other contrivance for receiving an impulse from undulations of air, a confused sensation of sound must have been communicated to it. It is necessary that music should be composed in a peculiar order for impressing the auditory nerve with its beauties, or even agreeable sounds; and therefore it may be said that music formed mechanically, by different instruments, or through the mechanical assistance given to them, would have been communicated in regular notes, or sounds, to the nerve, in whatever way this was disposed. Few will, I conceive, admit this opinion. The ear was formed in a line of peculiar mechanism, and capable of perceiving sounds, which must be emitted in a particular order; and all music has been adapted to this structure, and could not have been appreciated either as harmonious or agreeable without such adaptation. The labyrinth of birds is different from that of man, but it can appreciate music; for some species can imitate tunes,

and others the human language. Doubtless birds could always sing in tune if they could reason, and knew how to dispose the notes which the labyrinth is capable of receiving. But could they comprehend all the notes perceived by the human ear? Would not their different form of labyrinth require a different disposal of many of those heard by man? I conceive this would be necessary; for although their hearing be sufficient for judging of some notes, or tunes, yet a falling-off would be found, and variations required, in the same manner as different forms of notes are required in the execution of a piece of music by an assemblage of different instruments. We find variations in the labyrinth necessary for determining the capability of hearing in different animals, and in the structure of the eye for the required state of vision. The retina cannot of itself produce vision, but the mechanical powers of the eye are necessary for directing the rays of light to fall upon it according to the laws which regulate them; and this position is satisfactorily proved by the removal of the crystalline lens, and the consequent confusion of sight. We cannot observe these changes in the same manner in the ear, as its different parts cannot come sufficiently under our notice.

6, Tavistock-Square, Oct. 17th.

AN ESSAY

ON

ARTIFICIAL TEETH,

BY LEONARD KOECKER,

Surgeon-Dentist, Doctor in Medicine and Surgery.

[Continued from p. 109.]

On the indications and counter-indications of the use of Artificial Teeth.

THE proper decision of the question whether artificial teeth be positively indicated or not, is frequently dependent on very deliberate considerations, which can be estimated only by a perfect knowledge of all the changes and effects which are the result of time, age, and mastication, as well as of the diseases

and the natural curative powers of the teeth, and of the parts in any way related to them.

It is not an uncommon occurrence that one or more artificial teeth are inserted without any necessity, as where the loss of a tooth does not materially affect pronunciation or appearance, or where the case is of such a nature that the insertion of artificial teeth, instead of restoring the loss, inevitably increases the evil which it is intended to remedy, of which the following instance will afford an illustration:—

CASE II.

Mr. A. a medical gentleman of considerable celebrity, consulted me in Aug. 1827, about his teeth, some of which were loose from inflammation and great relaxation of their periosteum. On examination, I found he had lost his first and second molar teeth on each side of the upper jaw, which were replaced by artificial teeth carved in one piece of Hippopotamus tooth, fastened by clasps or springs to the bicuspid and wisdom teeth, which had thereby been rendered quite loose. Thus the effect of these artificial teeth was evidently not only the rapid destruction of the contiguous teeth, but instead of assisting in mastication, which was the only advantage that could be expected from the application of these molar teeth, as they could not be beneficial to either pronunciation or appearance, they positively interfered with the functions of the other teeth, by their injurious mechanical bearing, and the irritation which they necessarily produced.

The use of one or more artificial teeth is, however, properly indicated, and must be useful and necessary, if they can be applied without bearing too much upon the remaining teeth; and if they can be rendered an assistance either in mastication, pronunciation, or for the improvement of appearance. But as different defects and losses require separate restorative means, it is necessary to view the various indications of different circumstances, which will be best considered under the following heads:—1st. As single artificial teeth; 2d. small sets of two or more teeth; 3d. sets of the whole upper jaw; 4th. sets of the whole under jaw; 5th. whole sets for both jaws.

Single artificial teeth are never, under

any circumstances, calculated to assist mastication; the only advantage they afford is an improvement of pronunciation and appearance. I have, therefore, never considered it proper to restore the loss of only one molar or bicuspid tooth, but have confined this operation principally to the incisors or cuspidati; and the insertion of these teeth is often contra-indicated or liable to exceptions. If, for instance, a young individual under the age of 20 loses one of the cuspid teeth or lateral incisors, either in the upper or under jaw, I have in most instances dissuaded the patient from having a tooth inserted, and the vacancy has generally at length become so occupied by the remaining teeth, as to render the loss invisible, and an artificial tooth unnecessary; should such a loss take place, however, at a later period of life, and the vacant space be not of uncommonly small dimensions, the insertion of an artificial tooth may be useful, and more frequently in the upper than in the lower jaw.

The central incisors being the most conspicuous teeth of the mouth, and their loss the greatest detriment to appearance and enunciation, the absence of one of them is generally sufficiently indicative of the adoption of an artificial restorative; but should it be an under incisor, and the subject has the advantage of youth, I would in most instances permit the remaining teeth to occupy the vacant place.

Small sets of two or more artificial teeth, as well as single teeth, are very improperly intended for mastication; and if made for this purpose, will always tend rapidly to loosen the remaining teeth. This circumstance is too frequently disregarded by the dentist, as the case above related sufficiently proves; their utility must, therefore, be considered to extend, in every instance, exclusively to the improvement of pronunciation and appearance.

If only the molares and bicuspidati are lost, without the absence of some or all of the incisors or cuspidati, there is not sufficient reason for the use of artificial teeth; for neither appearance nor pronunciation will be materially benefited. Should, however, some of the incisors, or even but one of them, be part of the lost teeth, it may be proper to apply a set which substitutes all the lost incisors, cuspidati, and bicuspidati; and even sometimes a molar tooth

may be usefully included in the artificial apparatus.

Sets of artificial teeth for the whole upper jaw are sufficiently indicated not only when all upper teeth are lost, but even while some detached teeth are yet remaining. Such teeth are intended not only for appearance and speech, but also for mastication; and if they are in every respect judiciously constructed, the artificial apparatus will be found not only to produce all the advantages just stated to the greatest extent, but will also promote the preservation of the remaining upper teeth, by their support.

Sets of artificial teeth for the whole under jaw are, perhaps, of all, the most rarely required; for the loss of the teeth of the upper generally precedes that of the lower. Should, however, the case occur, a proper artificial substitute for the lost teeth would be even more desirable, and more positively indicated for the sake of appearance, mastication, and health, than in the former instance; and all the advantages just stated may be expected to the greatest extent.

A whole set of artificial teeth for the upper and under jaws is properly indicated not only when all the teeth are lost, but also when some of them still remain. In every instance in which the deficiency of molar teeth is of such a nature as to deprive the two jaws of that necessary support by which they are kept in their proper situation, and at a proper distance, a double set of teeth is very desirable. Thus when, for instance, the front teeth are still in a healthy condition, and the remaining molar and bicuspid teeth in both jaws are each without an antagonist, the whole weight of the two jaws must rest upon the incisor and cuspid teeth, which in most instances lap over each other, and by their oblique pressure must soon be rendered loose, unless they are supported by an artificial apparatus; but should this support of the upper and under incisor teeth be also absent in addition to the loss of every antagonist of the remaining upper or under small or large grinders, the indication for a double set of artificial teeth is still more decisive, and the advantages which have been stated to result from their judicious application in those cases in which whole sets for the upper or under jaw are separately inserted, may be as fully expected in the present instance.

Materials for the construction of Artificial Teeth.

Artificial teeth are frequently rendered a cause of injury, by their being prepared of improper materials—such as are either too soft or too hard, or liable to chemical changes of various kinds.

If such materials are too soft, they are liable to be very early eroded, in consequence of which they become discoloured, and a cause of caries to the natural teeth, and inflammation to the gums.

Any kind of bone not harder than the tooth of the elephant, and artificial teeth made of ivory, should therefore be avoided.

If the artificial teeth be made of any substance which is so hard as not to permit its proper adaptation, it is apt to produce inflammation, and consequent destruction of the parts with which it is placed in permanent contact.

Small sets of artificial teeth made of one piece of a kind of mineral, or terro-metallic preparation, may justly be ranked in this class. Repeated attempts have been made in Paris, London, and Philadelphia, to render such preparations more perfect; but success, I fear, must be considered hopeless, from the simple fact that it would be founded on principles contrary to the laws of chemistry; for such whole pieces being made of a soft paste, which is afterwards baked in the oven by a similar process to the manufacture of china, they are necessarily exposed to the changes in size and form which the heat produces.

From these considerations, the only kind of artificial teeth, and the materials for their preparation, that I use, are the teeth of the sea-horse, human teeth, and single mineral or terro-metallic teeth, mounted in various ways upon gold or platina.

All other metals, as lead, tin, and even silver, should be rejected, from their liability to chemical changes.

As the best materials for the construction of single artificial teeth, I would recommend the application of either human teeth or terro-metallic teeth only.

In the choice of these the dentist should be guided by the state of the mouth, and the tooth to which the artificial tooth is to be attached; and should the remaining teeth and the ge-

neral state of the mouth be healthy, the choice may be left to the patient; but if otherwise, a human tooth would be more particularly indicated.

These teeth are to be mounted, by various means, on golden plates, which have been previously well fitted to the gums, and are to be retained in their places by golden springs or clasps, attached to some of the remaining teeth. If such single teeth are well prepared, and attached with the requisite judgment, they may be used for many years, and frequently during life, without producing any injurious effects upon the remaining teeth, while they tend greatly to improve pronunciation and appearance.

As the best materials for the construction of small sets of two or more artificial teeth, the same rules as above may be considered most judicious, both as it regards their kind and their choice of the materials.

The materials for sets of artificial teeth for the whole upper jaw, and the mode in which they are constructed, must vary according to the circumstances in which they are applied.

If such an apparatus is applied when some of the incisor and molar teeth of the upper jaw remain in a good and healthy condition, it will be requisite to fit a gold plate to the gums, to which either natural or mineral teeth are so attached as to substitute every lost tooth; if, however, every tooth of the upper jaw has been lost, and the gums are in a perfectly healthy state, and the teeth of the under jaw also healthy, it may be considered a matter of choice to the patient which kind of the following artificial teeth might be most agreeable to his wishes and circumstances—namely, an apparatus constructed of natural or mineral teeth, mounted on a gold plate; or one carved of a single piece of Hippopotamus tooth, with or without human teeth in front. These artificial preparations are to be kept in their proper position by spiral springs, fixed at one of their extremities to the upper set, and at the other to a gold frame or band attached to the under molares and cuspidati, by means of three or four hooks or caps. In some cases of this kind I have, however, succeeded in applying an apparatus made entirely of sea-horse tooth, so as to be perfectly held in its place by suction or capillary attraction.

The materials best calculated for sets of artificial teeth for the whole under jaw, are the same as those for the upper maxilla.

Each of the preparations described may be applied under similar circumstances with equal convenience, without requiring any springs or other means to keep the set in its proper place, if it be well adapted to the gums and the upper teeth; and the choice of the kind of teeth should therefore be dependent on the same considerations as for the preparation of a set for the upper jaw.

The cases, however, in which such sets for the lower jaw are required are exceedingly rare, for in every instance that I have seen in which disease has caused the defect, the loss of the upper had invariably preceded that of the under teeth: still some accident or unusual circumstance renders its occurrence at least not impossible.

The materials best calculated for whole sets of artificial teeth for the upper and under jaw, as well as the modes of their preparation, must naturally be similar to those just stated.

For those cases where all upper and under teeth are lost, any one of the above-mentioned preparations may be adopted, although for the first time. A set of carved, either entirely of sea-horse or furnished with six or eight natural teeth in front may be the most desirable, from the great facility afforded by this mode to a perfect adaptation of the apparatus to the gums.

If, however, some few teeth remain by which the continuation of the arch of the artificial set is interrupted, a gold plate is requisite, on which single human or mineral teeth may be mounted, and the two pieces for the upper and under jaws kept in their proper situation by spiral springs, the two extremities of which are to be attached by swivels to the upper and under parts of the apparatus.

On the manner of constructing, and the means of attaching Artificial Teeth.

The preparation and mechanical construction of artificial teeth, as I have already observed, is attended with considerable difficulty; and their proper adaptation, as well as attachment to the other teeth and gums, requires the combined qualifications of mechanical and surgical skill. It is evident, therefore, that artificial teeth may be ren-

dered very injurious by unskilful management: if, for instance, they are not very well fitted to the gums, or if they bear upon such particular parts as are naturally more tender and irritable than others, as the edges of the gums surrounding the necks of the teeth; or if they violently and irregularly press against the remaining teeth they cannot fail to become the causes of disease.

Of the various means for their attachment of the natural teeth, nothing can be more injudicious than the use of any kind of ligature, either of gold wire, silk cord, or any other material of the kind; for such ligatures, by their stress upon the teeth to which they are attached, must inevitably produce great relaxation and inflammation of their sockets and periosteum, by which the teeth are soon rendered so loose as either to require extraction or to drop out. The use of ligatures for retaining artificial teeth is therefore, under all circumstances, objectionable, and should be entirely rejected. Even the best means for this purpose — namely, springs or clasps, applied without sufficient skill, are liable to produce the same effect as ligatures.

To obtain, therefore, the greatest possible advantage from artificial teeth, and to prevent their injurious consequences, I have adopted the following rules:—

Single artificial teeth should be intended for no other purpose than the improvement of appearance and pronunciation. Their assistance in mastication is neither necessary nor attainable, for every hard pressure upon the artificial tooth in mastication, in whatever direction it may be made, always acts upon the other teeth and gums.

In mounting single artificial teeth on the plate, I have taken care, 1st, to fit the basis or plate very exactly to the gums; 2dly, not to permit the edges of the gums which surround the two neighbouring teeth to be pressed or even touched by the plate; 3dly, to prevent the artificial tooth coming in contact with the two neighbouring teeth; 4thly, not to allow the artificial tooth to touch or strike in any direction against any of the under teeth when the mouth is shut. In their attachment I have invariably made use of no other means than two springs or clasps, fixed to such of the remaining teeth as seemed

to me best calculated to retain the artificial teeth.

I have already stated the pernicious effects of such springs as, from their injudicious preparation, produce unnatural or violent pressure upon the remaining teeth, and shall now proceed to point out their causes, and the means I have adopted for their prevention.

The usual way of fastening the springs to the two adjoining teeth, renders it difficult, from their shortness, to give to them the necessary elasticity. They, therefore, produce violent pressure, as they are too frequently made in such a manner as to act like a lever upon the natural teeth; but these are generally in a tender state, and are ill calculated to fulfil, in addition to their natural functions, the mechanical labour of supporting their artificial neighbour. I therefore have made it a point to avoid the tender teeth, by carrying the springs to some which are more distant, and which, from their health and situation, are better calculated to support the artificial teeth. I make it another rule not to let the springs bear upon the other teeth, or the edges of the gums, but make them rest upon some part of the mouth better calculated to bear the pressure, and less irritable and predisposed to inflammation, or any other kind of disease; and I also take particular care to prevent any violent pressure, by proportioning the strength of the spring to the length and distance of its attachment.

To render the pressure by which the springs are attached to the natural teeth perfectly harmless, I contrive to apply it in such a manner that the teeth are pressed neither in one nor other direction exclusively, which would inevitably cause relaxation and inflammation of the periosteum, sockets, and gums, but that they rather grasp the tooth, and press on two opposite sides, in such places as are perfectly sound; neither do I permit this pressure to be stronger than necessary. I also take particular care to give such elasticity to the springs that the artificial tooth may be removed and replaced without giving pain; and, lastly, I invariably make all artificial teeth, whether single or in sets, in such a manner that the patient is enabled to remove and replace them at will with facility.

Small sets of two or more artificial teeth are constructed and fastened under
101.—v.

the same principles as single teeth, with such deviations only as the different circumstances accompanying the case may require.

Sets of artificial teeth for the whole upper jaw, as already stated, should be prepared either entirely of a single piece of hippopotamus tooth, or of the same material, furnished with six or eight natural teeth in front; or of natural or mineral teeth mounted on a gold plate.

In the preparation of this apparatus, it is of great importance to consider that such teeth are intended not only for appearance and speech, but also for mastication. Particular care should be taken to adapt the plate as exactly as possible to the gums, and so as not to press on the natural teeth, if any should remain; and in those cases in which all the natural teeth are lost, I deem it preferable that all the upper teeth should meet the under by contact rather than in that direction in which the upper incisors lap over the under.

The set is to be retained in its place by means of two spiral springs, fastened to it by gold swivels at one extremity, and at the other to a gold frame, attached to the under teeth by means of gold hooks or caps. Various kinds of springs have been invented, of a more or less complicated construction, which are so much surpassed, in utility and simplicity, by the spiral springs, as not to deserve any notice.

Should there be sufficient indication for making use of a set which is to be kept in its place by capillary attraction, or by suction, it should be made of one piece of hippopotamus tooth; and the plate which rests upon the gums should be exactly fitted, and as broad as possible; and great care should be taken that in shutting the mouth the artificial teeth press equally upon all the under teeth. I have, by observing these cautions, been completely successful in several instances in the application of sets for the upper jaw in this manner, which is certainly very desirable, from its great simplicity and convenience.

Some dentists of advertising celebrity pretend to be able to construct all kinds of artificial teeth in such a manner as to be retained in their places by capillary attraction alone; such pretensions can be viewed only in the same light as those which attribute the power of curing every human malady with

one and the same patent medicine or nostrum.

Sets of artificial teeth for the whole under jaw should be made on the same principles as those of the upper jaw, but with the difference, that from their situation they would rarely, if ever, require any springs.

Whole sets of artificial teeth for the upper and under jaws are prepared and inserted under a great variety of circumstances, and they require to be regulated by those principles which I have endeavoured to establish for the separate preparation and insertion of artificial sets for the upper and under jaw.

[To be continued.]

MEDICAL AND SURGICAL ETHICS.

BY A PHYSICIAN*.

"Non omnia possumus omnes."

In reading over Mr. Lawrence's introductory lecture to a course of what he calls "Medical and Operative Surgery," it will be seen that that gentleman endeavours to level the distinction which has hitherto been supposed to subsist between the medical and surgical departments of the healing art. As this is a subject in which the public are parties, as well as physicians and the surgeons, the discussion of it cannot be confined to the theatre of St. Bartholomew's Hospital.

There are but two ways in which the distinction between medicine and surgery can be removed. One is, to render degrees in medicine in the universities unnecessary for the practice of medicine; the other, to render the university medical degree a necessary qualification for the practice of surgery. In fact, either to raise the standard of surgical education, or to lower that which is at present necessary for the education of the physician. In an age so intellectual as the present, to lower the standard of education in any department would be a startling proposition; the former alternative alluded to then only remains.

Should Mr. Lawrence, or any other well-educated surgeon of the London schools, be ambitious to obtain a degree in medicine, a term of four years' at-

tendance will be necessary in the universities of Dublin or of Edinburgh, before he can be admitted to examination, according to the statutes of these universities; and a longer period at the universities of Oxford or Cambridge. The College of Surgeons, should they wish, are competent to make and enforce such regulations among the members of their own corporation; and thus, and thus only, can they remove the distinction which subsists between medicine and surgery. That is,—by becoming themselves physicians. "Omne majus continet in se minus." The physician understands, or ought to understand, surgery; but the converse of the proposition does not hold,—surgery does not necessarily include medicine. When a medical degree shall be made necessary for surgeons, as well as physicians, practitioners may then follow the bent of their own inclinations, and practice medicine or surgery,—or both. Such an arrangement would secure to the public the benefit of scientific acquirements, without the charlatanism of pretension founded on academic rights or privileges.

That four years' study in a university, superadded to a surgical education, would ensure to the public good medical practitioners, there can be no doubt; therefore, so far as the public are concerned, the plan would be a good one; and as such an expense of time and money would exclude from the profession many, who, according to the present system, become surgeons, and consequently medical practitioners, the plan would be beneficial to all those who could afford to take medical degrees. But, besides the illiberality of excluding from practice individuals who may possess great talent, although they may have little money—whose minds may be large, though their means are small, we should still find that something like the present subdivision of labour would be necessary. But surgery, in its literal acceptance of operative, which some consider too narrow to bound the views of the surgeon, is found practically too comprehensive. We find oculists, aurists, and dentists, who are all scions of surgery, make fortunes in London, although confining their practice to particular departments of surgery. Even the manipulation of spines, particularly those of young ladies, if adroitly performed, may be sufficient, as a department of surgery, to make the for-

* Willing to promote free discussion, we have given insertion to the observations of our Edinburgh correspondent; at the same time we must say, that he appears to us to stretch Mr. Lawrence's meaning beyond what a fair interpretation of the text admits.—ED. G.

tune of a specious practitioner. How much more befitting the march of intellect and the progression of science, for the regular and scientific surgeon to collect together these scattered fragments of surgery, properly so called (operative), and to constitute one perfect surgical whole, to occupy his time and talents, than to allow the oculist, aurist, dentist, and even the spine-manipulator, to strip him by piecemeal of the lucrative portions of his own profession, and then to make incursions himself into the province of the physician, and under the quaint designation of "medical surgery," to endeavour to assume the privileges of the physician without taking care previously to possess his knowledge.

Every one who has taken a degree in medicine in a regular university, has attended courses of lectures on at least six or seven sciences connected with medicine. In every and all of these sciences he must have been prepared for examination, and may have been examined in all of them, before he got his degree. But should the same individual aspire to become a teacher, or should he by interest, or even talent, obtain a professor's chair, he will find one science amply sufficient to employ all his mental powers. The public seem to make a similar judgment in the departments of surgery to which I have already adverted; and although Mr. Lawrence may understand the eyes, ears, and teeth, and even the spine, as well as the professed oculist, aurist, dentist, and spine-manipulator, the public cannot be brought practically to think so.

But let us suppose for a moment that Mr. Lawrence and the other hospital-surgeons of the metropolis, like most of those of Dublin and Edinburgh, were regular doctors in medicine. They would still find it necessary (like those of Dublin and Edinburgh) to sink the M.D. while practising surgery. It is impossible to combine in one individual all the requisites in the wide range of medicine and surgery. I admit that no man can know too much of his profession, or of the sciences connected with it; nor can he possess too much general information; but I am quite certain that he cannot practice medicine and surgery in all their various departments, nor will the public afford him the opportunity.

In conclusion, as Mr. Lawrence

and the other members of the Council of the Royal College of Surgeons in London, are not likely to concede the privileges of their college to medical men who have not taken a diploma in surgery, nor are likely to recognise their right to practice it; so are physicians not likely to recognise the right of surgeons to practice medicine, until they shall have taken a medical degree in some recognised university. It would be well, however, and would be for the benefit of all parties—the public included, that some conventional etiquette were established, regulating the intercourse between physicians and surgeons. Were this done in the great public hospitals, the etiquette established there would soon extend to the relations of private practice, and put an end to jarring claims and pretensions, which are any thing but creditable to medical science.

Edinburgh, Oct. 1829.

ANALYSES & NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

A New Method of Treating Burns and Scalds, and certain Cutaneous Eruptions. Parts I. II. and III. By MICHAEL WARD, M.D. S.R.C.S.L. late Surgeon to the Manchester Infirmary, &c.

Among the many extraordinary productions in the shape of medical writings which come under our notice, the one which lies before us stands pre-eminent. In typography it is the most curious intermixture of roman, capitals, and italics, we have ever witnessed; and in medicine, the most felicitous blending of cases, comments, correspondence, notes, corrections, and commendations, that can possibly be imagined—a model of scientific arrangement and monument of professional ingenuity. There is literally nothing new in it, and yet, *mirabile dictu*, that nothing is divided into three parts. The whole of the volume, such as it is, may truly be said to be contained in the following short extract, which also has the advantage of illustrating the author's method of attracting notice, by the arrangement of the types, to what cer-

tainly would never command attention by the value of the matter:—

“We will suppose the clothes of some person, *no matter how old or young*, to have taken fire, and to have continued burning some time before the fire could be extinguished; or, secondly, that one or more human beings have escaped or been rescued from a House, a Factory, or other Building in flames, but not until they had sustained considerable, perhaps irreparable injury from the fire; or, thirdly, that one or more persons have been exposed to the action of fire by an explosion of gunpowder, inflammable air in a Coal Mine, or any other cause; or, lastly, that some unfortunate individual has fallen into a vessel of boiling liquor in a Brewhouse or Distillery; accidents which are well known to be as frequent as they are dreadful. In all these cases, (and of course in all those of the same nature, *but of less extent and magnitude*,) the *first* object will be, (after having laid the patient upon a bed or sofa,) *without a moment's loss of time to take off the clothes* AND APPLY BREAD FLOUR, BY MEANS OF A COMMON KITCHEN DREDGER, PLENTIFULLY, AND AS EXPEDITIOUSLY AS POSSIBLE, TO THE WHOLE OF THE BURNED OR SCALDED SURFACE, and this being properly and sufficiently done, carefully applying clean dry linen cloths immediately over the flour, and such bed clothes or other coverings as may be required to keep the patient comfortably warm, but not too hot.”

Such is the discovery which is to hand down the author's name to posterity; and, meantime, has secured him the applause of Mr. Tatham, the Reverend Mr. H. Penny, and Mrs. Hyde. The last, says Dr. Ward, “is an honour to her sex; whose praises, supposing for a moment I would be said to merit them,—are fame.” So great is the value of the remedy, that one young lady, a member of a large family, who, after a dreadful burn, was so efficiently dusted with the “dredger,” as speedily to become the “flower of the flock.” Describing one of these cases, the author exclaims—“What might be the ideas and sensations of COLUMBUS when his eyes first caught a glimpse of AMERICA, I shall not presume to say, but it is not possible, I humbly conceive, for them to have been more poignant, or of a more pleasing and gratifying description, than mine at that moment.”

Having thus followed the learned author to the other side of the Atlantic, we shall leave him there; nor need we regret this, for he will remember that his friend Columbus, when he returned, was rather ungratefully treated; and notwithstanding all the Doctor lays claim to, it is just possible that he might meet with a similar fate, were we to extend our remarks.

A Practical Treatise on Acute Abdominal and Pelvic Inflammation; containing a comprehensive clinical View of Inflammation of the Stomach, Bowels, Peritoneum, Uterus, &c. with a certain and expeditious Method of Cure. By DAVID NICHOLAS BATES, Medical Practitioner.

THE tendency of this little work, so far as its influence may extend, must be injurious. It is true, it contains nothing calculated to push it into general notice; but as some may, by possibility, be guided by the precepts it contains, we think it right to enter our protest against them.

The description of inflammation is meagre, but not otherwise remarkable: of the treatment we must speak differently;—it is not only deficient, but so erroneous that we could not have imagined it to have emanated from a practitioner who had seen even half a dozen cases of the disease on which he writes, had he not expressly stated (p. 48) that there is no part of it which has not been confirmed by “reiterated experience.” Speaking of the treatment, Mr. Bates says, “This may be successfully conducted in two ways; the *first*, by enema; the *second*, by medicines taken by the mouth; or the former may be brought to the aid of the latter, should it not prove quickly effectual in removing the disease; or the *two plans of treatment* may be conjoined; although, when the former is used, such a combination will not be necessary, as its success is certain.”

We read this passage several times over before we could persuade ourselves that there was no mistake or misapprehension on our part.—Two methods of treating *acute abdominal inflammation*, “the first by enema! the second by medicines taken by the mouth”!! and again, when the former used “success is certain”!!!

Absurd as this is, it is still more ridi-

culous to find that the first part of the plan, "by enema," is, to take a pint of blood from the arm, in all cases where the strength will admit of it. After this, from one to two drachms of tincture of opium is to be administered, in the form of clyster, in the decoctum amyli, and the enema to be repeated in twelve hours, if necessary. Along with these remedies, the horizontal posture, leeches, and fomentations to the belly, and low diet, are recommended: and thus does Mr. Bates treat acute inflammation of the abdominal viscera.

That this method will succeed in very mild and favourable cases, we have no doubt; neither have we the slightest hesitation in affirming, that where it does, the cure depends—not upon the opiate clyster, but the venesection, leeches, and fomentations.

The second plan, or that by medicines administered by the mouth, likewise commences with the abstraction of a pint of blood; after which is to be given a bolus containing one grain of opium, and a like quantity of antimonial powder and pulvis acaciæ: this to be repeated in an hour, and then continued every two hours, till the pain ceases. But if, after the tenth or twelfth bolus, decided relief be not obtained, recourse must be had to the opiate enema. In Dr. Armstrong's paper (Transactions of the Apothecaries) wherein he advocated the treatment of abdominal inflammation by opium, he had the prudence to direct that the patient should be largely bled two, or even three times the first day, a dose of opium of about two grains being given after each venesection; but Mr. Bates "out-Herods Herod," for he only allows us to bleed once while we give ten or twelve grains of opium by the mouth, and wind up by a drachm or two *per anum*. A yet greater ignorance of the action of medicines is manifested by his condemnation of calomel, because it "is apt to disagree with a scrophulous constitution." Thus we are to avoid the most powerful means, next to bleeding, we possess, of arresting a most dangerous inflammation, lest it should "disagree" with the patient. "Hydrargi submuriæ, either alone, or combined with any other purgative, must be totally excluded." (p. 47.)

The author afterwards proceeds to indulge in some theoretical views with regard to the nature of inflammation—

the state of the blood-vessels—the influence of the nerves, &c. To these we have no objection; every man has a right to have "his say" upon these topics as well as his neighbours; it is only against the practice we protest. So far as his brethren are concerned, Mr. Bates has little to fear, for we sincerely believe no one will be rash enough to follow his advice; but, as regards himself and his patients, he will be a lucky man if he does not one day find, to his cost, that the mode of curing acute inflammation of the abdominal viscera does not consist in binding up the bowels with opium administered by either extremity.

An Account of the Mode of performing the Lateral Operation of Lithotomy; with Illustrations. By EDWARD STANLEY, Assistant Surgeon, and Lecturer on Anatomy and Physiology, at St. Bartholomew's Hospital.

This work consists of a set of plates representing the parts concerned in lithotomy, in all their aspects; and of a description of the mode of performing the lateral operation. The plates are exceedingly well done on stone, with the arteries coloured; and the introductory observations, without any aim at novelty, contain a simple and perspicuous explanation of the different steps of the proceeding. The work will be of great use, both to the student who wishes to attain precise ideas on the subject, and to the practitioner who is desirous of refreshing his memory on the points to which it refers.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."—CICERO.

MARCH OF INTELLECT.

It is a consideration as humiliating as it is true, that while we are flattering ourselves with the progress the age is making in science, knowledge, and

improvement, instances are daily occurring of the regeneration of superstitions and follies, as gross as those we condemned in what we affect to call less enlightened times.

The tales invented to stimulate political fervour lose something of their grossness in the consideration of the vast and mighty interests with which they were blended, and are somewhat excused by the excited imagination of the people. The miserable tales and false miracles which disgraced the contests of the Jansenists and Quietists are forgotten; while the writings of Pascal and of Quesnel remain to redeem, from the lowest contempt, their disciples who invented, and the multitude who greedily caught at, wonders so ill contrived, that some degree of credulity appears to be required ere the fact of their belief be established. In our own country, the superstition of the Cock-lane ghost belongs, we fondly believe, to an æra which the progress of education and improvement in philosophy has left at an immeasurable distance.

Let us examine whether passing events justify this supposed superiority. The Cock-lane ghost was surely a harmless superstition compared with the blasphemous adventures of Joanna Southcote. The miraculous cure of the niece of Pascal, believed by the devout, in the time of Louis IV. may fairly be excused, when the miracles of Prince Hohenlohe have found credence in England among not a few of the enlightened subjects of King George the Fourth. It would be needless to mention the minor fables of the Princess Caraboo, or the Tuthury woman who lived for so many weeks without food.

Among not a few of the superstitions which have afflicted mankind, may be reckoned the faith in specifics or modes of cure, recommended principally by the pain they inflict—by their peculiarity or their indecency. Such faith is

more excusable, as it takes its rise from the infirmity of human nature—the gratification these means hold out to the longings of the afflicted relative or the suffering patient. The occasional prevalence of such follies is a subject of sincere sorrow to those who cultivate the healing art: the cheat fails not in time to be discovered, and the science suffers. The real advantages—the incalculable comforts which the proper administration of the medical art affords, are lost in the disappointment of those who aim at all or nothing.

But how does this apply to the present time. The *elixir vitæ* sleeps in the same tomb with alchemy and judicial astrology—the visions of Cagliostro, and, we had hoped, the works of Puysegur, might be referred to the good old times before the Revolution. People now never seriously think of repairing to cow-houses, or being stripped naked and buried in loose mould before their time, for the cure of phthisis. The solvent of Mrs. Stevens, though approved and rewarded by the collective wisdom of the Parliament, has long ceased to be heard of; and, in truth, specifics for the instantaneous cure of disease exist only like the orvietan in the novels of Sir Walter Scott, and patients only awake perfectly well from a critical sleep in nervous fever, to content the languishing wishes of the hero of a romance.

Still at this very moment—in this enlightened metropolis—within a very short distance of that citadel of intellect, the University of London—a man flourishes by what he calls curing consumption: he has a specific which he will not disclose, which restores to life and health, and society, those unhappy victims of disease who have already large excavations in the lungs from the supuration of tubercles. To those who have witnessed the appearances after death in fatal cases of this disease, such

a pretension is fit only to excite ridicule; but it becomes a very serious matter when it is so far believed that persons actually set about defending such charlatanism in print. The arguments are such as these—"Because you cannot discover a remedy yourself, can no other man? but the medical profession was ever illiberal and envious. Look at the remedies invented by Empirics—the first use of bark was a species of Empiricism—the powders of Drs. Dover and James, and other quack medicines, have long since been admitted into the Pharmacopœia—remember the opposition to vaccination."

All this is very plausible: nobody denies that accidental circumstances have first brought some active medicines into notice; but great care, and the experience of ages, have been necessary to determine their value, and regulate their employment. Vaccination was proposed on scientific principles, and there was nothing contrary to the laws of pathology, as then understood. The discovery was an imperishable monument of the perfectibility of our art by the just application of talents, and by induction from established facts, combined with observation.

That some of the persons who have consulted Quacks have afterwards been better, it is unnecessary to deny. A host of invalids are always floating about London—some seeking relief for evils they never had, others trying to restore an appetite lost by indulgence, and which would be cured by abstinence from high-seasoned viands and luxurious living; and others broken down by labour, which has failed to conduct them to the goal of their wishes. Many of these, doubtless, find their way to Mr. St. John Long, and feel relieved for a time by the hope that they have discovered the nostrum which has long disappointed their search.

Let those who, during the war, practised at Bristol and in Devonshire, say

how many of the patients who applied to them were really cases of consumption; how many had winter-cough; how many asthma; how many disordered stomachs; how many young females at 16, nearly the martyrs of fashionable education, and the eternal drilling of accomplishments, recovered, of supposed consumption, by air, exercise, and good diet.

Some persons live several years with undoubted consumption. The destruction of the lungs is partial; sufficient is left for the purposes of life—of an invalid life, scarcely worth having. Regimen, and the occasional use of remedies, fitted to the particular changes of the case, prolong existence to a much longer period than is generally known. Such cases are often relieved by blistering, and doubtless are so by the excoriating applications of the curer of consumption; but that there is any remedy, which he or any other man has to repair the destroyed lungs, or remove the indurated masses which obstruct their functions, is a fable as gross as those we have alluded to in the tales which we laugh at of former times—the mixed offspring of knavery and credulity.

But is this all? shade of Haygarth* believe it not. The superstition is revived which you so successfully disproved, and with it the reign of mysticism. Magnetism—mesmerism, actually exists. Puysegur again lives and reigns; and the cures which you effected with two pieces of coloured wood, and the wonders which you performed by enlisting the imagination in your cause, are forgotten.

After this shall we rail at ancient superstition, and glorify ourselves on the march of intellect in the nineteenth century?

* See the invaluable pamphlet entitled "On the Imagination as a cause and cure of Disorders in the Human Body, exemplified by Fictitious Tractors and Epidemical Convulsions. By (the late) J. Haygarth, M.D. F.R.S."

MR. EARLE AND THE LANCET.

THE manner in which Mr. Earle was formerly spoken of by a contemporary journalist, forms an amusing contrast to the praise which has recently been bestowed upon him. Some, we believe, went so far as to imagine that Mr. Earle had in some manner courted the *Lancet*, or at all events, that he was gratified with the commendations he received in its pages. They did him wrong: the change alluded to was none of his seeking, but was regarded by him with the contempt which it deserved. No man was more uniformly, decidedly, and fearlessly opposed to the system of detraction, when it was on the ascendant, and to have listened to the voice of the slanderer now that all who make the slightest pretence to respectability shrink from any—even an implied connexion with him, as a stain upon their character, would indeed have been absurd.

But at all events, the matter is set at rest by what Mr. Earle took occasion to state on Saturday evening with regard to the publication of his Clinical Lectures.

"They were instituted," said Mr. Earle, "for the benefit of pupils actually attending the hospital practice.

"As the observations apply to the cases in the wards, they cannot be of any importance to the medical public who have not access to those patients, and as respects pupils actually attending the practice and the lectures, it must be quite superfluous to publish them.

"As the observations are often delivered without much time for preparation, and as they are given without the slightest reserve, it being my wish to open my mind freely, and state every circumstance as it occurred to me, it follows that many remarks may fall from me which I should not wish to have recorded. It will therefore impose a restraint upon me on many occasions, when it might be interesting to the student that I should be more communicative.

"All these fully sufficient and valid objections apply to the publication of my Lectures in any periodical. But

I have others, and even stronger, to urge against their being published in a work which for a series of years has persecuted me most maliciously, and which was employed as an instrument to injure or destroy my reputation; and thus, as far as it was able, to deprive me of the means of living and providing for my family.

"If I could flatter myself that any remarks of mine were calculated to promote the general good, or advance the cause of science, I should certainly wish to select some purer channel for communicating them.

"It may, and indeed has been, urged, that the editor is now sensible that he has injured me most unjustly, and THAT HE IS DESIROUS OF MAKING SOME REPARATION!!! I can only solemnly declare that I have not sought his praises any more than I have merited his reproaches. I cannot, however, forget—(I should be more or less than man if I did)—the lavish abuse and ribaldry with which I was weekly assailed; and I cannot, therefore, but doubt the purity of his present professions—'*Timeo Danaos etiam dona ferentes.*'

"If I have of late been spoken of in a different strain, I feel confident that I owe it to the honesty of the present reporter, and not to any forbearance on the part of the editor. I am happy to embrace this opportunity of stating that I believe that the gentleman who has for some time acted as reporter for the journal in question, has faithfully discharged his duty. But, gentlemen, I have been assured from different sources that the editor of that journal has *always* entertained respect for me. Until lately he certainly adopted an extraordinary mode of evincing it. I am willing, however, to believe, that he has respected me, for I am confident that I have never given him cause to entertain sentiments of an opposite nature. I hope, by my conduct on the present, and all future occasions, to compel him still to do so; but to accomplish this, I must not be wanting in that respect which is due to myself. I am well aware that, in adopting the present course, I am again laying myself open to his attacks: I am equally well aware, that by pursuing an opposite course, and by furnishing, as requested, notes of my lectures, and correcting the press, as some others have done, I might ensure some degree of commendation; but I trust that I shall never be induced

to seek reputation at the sacrifice of professional character—at the sacrifice of my independence—at the sacrifice of that consistency which I persuade myself has hitherto regulated my conduct—and, above all, at the sacrifice of the *mens sibi conscia recti*, which has supported me under all the attacks and aspersions his falsehood and malignity could invent.”

This address was received by loud and long-continued cheers from the pupils, among whom, it is only justice to say, but one feeling—that of unanimous and hearty concurrence—prevailed. What must be the character of a work in which no honourable man can suffer himself to be praised, lest his character be injured by it, and the public denunciation of which is hailed by the enthusiastic approbation of a numerous class!

We had sent instructions to our reporter to attend for the purpose of taking the lecture, which consisted of the description of an ingenious instrument of Baron Heurteloup's, for washing out the bladder in lithotomy, and of some valuable observations on vesico-vaginal fistula; but, finding that Mr. Earle did not wish them to be published, of course we cannot give them insertion.

We leave our worthy contemporary to congratulate himself upon the very respectable figure he cuts in this transaction. He one day ridicules, calumniates, and abuses Mr. Earle, because he thinks it will serve his purpose to do so. Next day he imagines an opposite course more likely to promote his interest, and therefore he be-praises, and fawns upon him till he thinks he has *smoothed* him sufficiently. He then ventures upon more direct advances: he sinks the threatening of the bully in the whining of the sycophant; commits himself—and is exposed. No experience ever enables such a person to comprehend the feelings of a gentleman.

MR. LAWRENCE'S LECTURES.

MR. LAWRENCE has withdrawn from all the Journals the permission he had granted to publish his lectures. “Circumstances,” he says, “had rendered it absolutely necessary for me to take this step.” Thus, then, ends the disgraceful effort on the part of the Lancet to make the public believe that Mr. Lawrence corrected his lectures for that Journal; and thus has Wakley drawn upon himself a contradiction of the falsehood from the very quarter he would most have avoided.

SIR GILBERT BLANE'S MEDALS.

THIS distinguished octogenerian physician, who began his long and honourable career in the naval service, has appropriated a sum of money for the purpose of bestowing gold medals on those surgeons of the navy whose medical and surgical journals shall be found to evince the greatest share of professional zeal and knowledge. A certain number of these journals is to be selected by the Medical Commissioners, and by them transmitted to the Presidents of the Colleges of Physicians and Surgeons, who are to be the umpires. The medals are to be awarded every two years.

The idea is well calculated to excite emulation in the medical department of the navy; and the name of Sir Gilbert Blane, already so highly respected, will be handed down in grateful remembrance to those who come hereafter in a service which has done so much to improve and to advance.

PROCEEDINGS OF SOCIETIES.

THE various Medical Societies of the Metropolis have resumed their usual meetings for the season. It is not our intention to do more than notice from

time to time any thing of interest which may occur.

HUNTERIAN SOCIETY.

At a late meeting Dr. F. Ramsbottom introduced the girl whose scapula had been almost wholly removed by Mr. Luke, on account of its being the seat of medullary sarcoma. The case and operation were formerly related to the Society, and have been reported in the Gazette. The wound had completely cicatrized, and the motions of the arm were not greatly affected. There was no indication of a return of the disease, or of its appearance in any other part.

WESTMINSTER MEDICAL SOCIETY.

DR. GRANVILLE and Mr. BACOT have been elected Presidents in the room of Dr. J. Somerville and Mr. Arnott, who go out by rotation. The meetings have been well attended, but the discussions heavy: the speaking is too much limited to two or three members, who favour the Society with their opinions on every subject. We subjoin a little squib which has been sent us; but we fear the point will scarcely be understood by those who were not present.

"INTERESTING" DEBATE.

To the Editor of the London Medical Gazette.

Wimpole Street, Nov. 3.

SIR,

Though I am doubtful whether you will admit a communication from one of the weaker sex into your Journal, (which I occasionally peruse in my husband's study), I venture to address a few lines to you on a subject deeply interesting to me; and, I am sure, to the wives of other medical men. You must know, sir, that I have been married but a few short months to one of "the profession," and during that time have had no reason to complain of unkindness, or to suspect that other "society" was preferred to mine. But, sir, last Saturday evening, judge of my feelings when I saw my husband suddenly start up, and order tea before the usual hour, as he had to go to the "society" in Sackville Street. At first I tried to dissuade him, but at length yielded, with the best

grace I could, when he assured me that the meeting was most important; that he had already lost two most interesting debates, and had thus forfeited a great benefit to himself. He went, sir, and left me to meditate on the sacrifices which the true lovers of science make in the pursuit of their object.

After an absence of two hours, or rather more, the well known knock at the door announced his return, and in proportion as I had been vexed at his absence, was I now anxious to draw from him as much of the "interesting debate" as possible. Now comes my grievance, for with some hesitation he reluctantly confessed, that after some interesting observations (*interesting*, I find, is the word) on the whims and foibles of our sex, under the learned name of hysteria, the "debate" opened with a solemn silence, which he affirms lasted three quarters of an hour; during which time my husband fell asleep; and of all that passed, merely heard at intervals a gentleman knocking the table with his fist, and who appeared to be in a monstrous passion, nobody knew about what; while, during the intervals, occasionally the words—subject—barren—prolific—pregnant, &c. dropt from the lips of an "honorable" gentleman in a huge red chair. He was at last fully awake by one of the members protesting against the chairman being allowed to call for spirits, as contrary to the custom, if not against a positive law of the society. After this followed a naughty story about two men holding an officer's "lady," screaming upon the floor, till a Doctor somebody came to her assistance. He did not catch the remainder, being scarcely awake; but I think there is quite enough of the story as it is. Yet only think of a gentleman, near the president, having the simplicity to ask "what was to be done in such a case." So, then, this is what is meant by a "case." I did not quite like the words "society," "meeting," and "interesting debate," but I had no idea it had been any thing half so bad as this. Yet what better could be expected when the chairman himself had recourse to spirits; and, as my husband told me, gave the noisy member "a rap over the knuckles."

I hope, that as an impartial Journalist, you will give insertion to this; and for my part, while I find that the "interesting debates" are on such impro-

per subjects, I shall use my utmost endeavours to persuade the wives of other medical gentlemen to keep the "members" at home, where they may learn quite as much without being corrupted by the indecorous remarks of those who would persuade them to stay out at nights.

Your obedient servant,
LUCINA.

HOSPITAL REPORTS.

HOTEL DIEU.

Fracture of the Vertebral Column— Symptoms of Compression of the Cord —complete Recovery.

EXAMPLES of complete recovery after fracture of the vertebral column, are rare; we therefore give insertion to the following, which has very recently occurred in the Hotel Dieu, Paris.

L. Jean-Marie, a mason, aged 28, of sanguineous temperament and robust frame, was admitted at the above hospital Sept. 3. On the 27th of August he fell from the second floor of a house, and fractured his back, at the site of the tenth dorsal vertebra: the existence of fracture was ascertained by M. Bernard: the patient had been bled four times during six days, by a medical man who was called immediately after the accident. At the moment of the fall he became insensible, but this state soon passed away, and it was not till the second day that signs of compression were evinced by paralysis of the left inferior extremity, at which time symptoms of inflammation had come on. On his arrival at the Hotel Dieu he was bled again.

Sept. 4.—At the visit to-day the fracture of the vertebral column was manifested by a considerable projection of the last dorsal vertebra, which formed a curve of three inches, the convexity of which was towards the right, and, of course, the concavity to the left. No attempt was made to verify the existence of fracture, by producing crepitus, as it was feared by so doing the fragments might be thrown into a less favourable position. The left leg was without sense or motion; the right retained its functions, as did the bladder and rectum. The patient was placed in

a position as nearly horizontal as possible, the loins being supported on a hollow pillow. A sheet was folded like a cravat, and passing across his chest, was fixed to the bars of the bed, so as to retain him in the recumbent posture. During the night (4-5th) he had delirium, with febrile reaction. He was bled to the extent of three palets, and twenty-five leeches were applied in the course of the jugulars.

5th.—The patient calmer, notwithstanding which a strait waistcoat, which had been put on the preceding night, was retained. He was cupped on each side of the spinal column, at the seat of injury.

7th.—The cerebral symptoms gone, but the paralysis of left lower extremity continues: cupping repeated as before.

From this time gradual improvement took place, but the patient was rigorously prevented from moving, and no examination of the fracture ventured upon. By degrees the sensibility and power of motion returned in the paralyzed limb: by the end of September the former was nearly restored, but the latter came more slowly.

Oct. 14th.—The sensibility and power of motion are now nearly the same on the left side as the other: the projection of the vertebræ, though still perceptible, is much less than before. He has not yet been allowed to move from his bed, but his recovery is regarded as secure.—*La Clinique.*

WESMINSTER HOSPITAL.

Retention of Urine.

ROBERT BURROWS, æt. 30, admitted under Mr. White, with retention of urine, the evening of October 17.

This patient had a gonorrhœa two years ago, and was in the habit of passing a bougie himself. He had at this time, for a few days, great difficulty in voiding his urine. Three weeks back he perceived he had a fresh attack of gonorrhœa, and he again began to pass his bougie. On Friday Mr. White saw him, and with some difficulty passed a gum elastic catheter, and relieved him. At one o'clock on Saturday morning Mr. White was again called to him, and passed a small silver catheter. He saw him during the day, and attempted in vain to get into the bladder; there was evidently inflammation, and great irritation of the whole canal. He was admitted into the hospital in the evening, not having passed any water for eighteen hours.

He was bled immediately to ℥xvj . He complained of being in great pain; bladder moderately distended, and painful on pressure; pulse regular, but hard; countenance anxious. He was put into a warm bath for half an hour, and immediately after he was taken out, ten grains of *Pulvis Ipecacuanhæ c.* were administered. This he vomited; it was therefore repeated in a short time, when it was retained. An enema, with house medicine, was also given.

Eleven, P.M.—He has had two doses of the Dover's powder, and been again into the bath until he nearly fainted. A catheter was endeavoured to be passed very gently, but after a short time the attempt was given up. The instrument was stopped by a stricture about three inches down the urethra. Ordered fomentations and *Pulv. Ipecacuan. c. gr. x.* every hour. Injection to be repeated.

18th, ten A.M.—At two o'clock in the morning he passed about three ounces of water, from which he received great relief; and at three o'clock about two ounces more: he then seemed disposed to sleep. He has had the injections repeated thrice during the night, and continued the powders. He is in less pain this morning than last night; tongue clean; bowels have been tolerably freely acted upon. Complains of pain on pressure of the abdomen; but the tenseness and tenderness of the perineum are in some degree diminished; he is not aware of having passed any water since three o'clock. Mr. White has just seen him, and ordered the fomentations to be continued. Powders omitted for the present, and 20 leeches to be applied to the perineum. His head has been slightly affected by the powders, and during the night he vomited once.

Vespere.—Mr. White has succeeded in passing a small flexible catheter into the bladder, and about a quart of strongly ammoniacal urine has been withdrawn. The catheter is fastened in. The tumefaction and tenderness of the perineum and penis are considerably diminished.

19th.—He is free from pain; the catheter is kept in; his bowels are rather confined; tongue pale, but clean; pulse natural, and no pain on pressure of the abdomen. He says there is considerable discharge from the urethra.

20th.—Going on well.

21st.—The catheter is still continued in; he complains of pain in the perineum, and there is some appearance of a small abscess forming.

Ol. Ricini ℥iss. st. sumend.

23d.—He has had a poultice applied to the perineum; complains of great pain at that part.

24th.—The abscess has broken; he is much relieved. The catheter has been removed; it had become clogged with mucus.

25th.—He passes his urine very freely—more so, he says, than he has done for a long time; and is free from pain of any kind.

Disease of the Stomach—Ejection of a singular mass by Vomiting.

Susan Hickman, æt. 43, admitted October 21, under Dr. Roe.

This patient states that she has enjoyed good health until within the last five years, not recollecting any severe illness. She has never had any family, and is not married; her constitution not very strong. She commenced menstruating at the age of 20, and continued to be very regular till five years ago, when her menses stopped entirely: her periods occurred every month, and with great regularity; a fortnight after the last she was seized with a continual sickness, and after a time had very severe vomitings. Soon after this she felt her stomach very sore, and had a difficulty of swallowing hard food; in attempting to do so, she felt it stick near the end of the œsophagus, then proceeding a little lower, and at last, when fairly in the stomach, giving her pain, as though it was passing the whole length of the viscus. In vomiting there seemed to be the same obstruction at the cardiac orifice, and a little higher in the œsophagus. Sometimes, in swallowing, the food arrived at this point, and was then rejected; liquids, or soft moistened food, passed without the same difficulty. She was admitted about this time into the Westminster Hospital, under Sir G. Tuthill, but remained only a week; and when she went out says she was in some degree relieved. About a year after this she came a second time, and was again admitted under Sir George Tuthill. She remained nearly five months, suffering severely from pain in her stomach, violent vomiting, and severe cough. She then went out, still suffering, in a less degree, from the same symptoms. She has never, since the first attack, been more than a day free from vomiting, and always brought up a yellow mucilaginous matter; more frequently three or four times a day, generally after eating, and sometimes without. She states that her whole food, for the last four years, has consisted of beef-tea, mutton-broth, water-gruel, and arrow-root.

On Tuesday, October 20th, in the evening, she had a severe fit of vomiting, and felt nearly choked, when a yellow body, resembling a fish in form, was thrown up, and fell upon the floor: the people *swear* it moved for some seconds afterwards, but it is evidently impossible. It is merely a mass of disorganized matter, matted and rolled together into the form described. It is about five inches long, tolerably smooth and compact; one extremity very much resembling the head of a fish, having also two black specks in the situation of the eyes.

She has felt greatly relieved ever since, experiencing scarcely any pain in her stomach, and swallowing bread without any difficulty. She was very sick during the whole of next day, but has ever since been totally free from sickness.

She has a very small thin pulse. Her bowels have generally been very relaxed, but are confined this week. She has been subject for five years to a severe cough, and some difficulty of breathing, which increases at different times. She has also, during that time, made a larger quantity of urine than natural, but can give no precise idea of how much; and states, also, that during fits of coughing, the urine is expelled involuntarily. She refers all her ills and complaints to precisely the same period five years back, but it is doubtful whether her accuracy may be fully depended upon.

GUY'S HOSPITAL.

Large Fungoid Excrescence in the site of a Cicatrix—Removed.

THOMAS MEDHURST, aged 35, formerly a sailor, was admitted into this hospital on the 16th September last, under the care of Mr. Key, for the treatment of a hard tumor, with fungoid excrescence, situated across the front of the thigh, close to the knee. He states that 15 years ago, when at sea, he fell violently against a beam and struck his thigh; the immediate effects of this bruise soon subsided; but about two years and a half after this he perceived on the spot a small hard cutaneous lump, unattended at first with pain. It gradually increased in size, until it gave rise to shooting pains, which were always worse at night.

Three years ago this was removed by the knife, and the wound healed very well; notwithstanding which ulceration of the cicatrix took place six months afterwards, when the disease recommenced, and has gradually increased to its present state, viz. a hard subcutaneous tumor, about four inches long, and about half as broad, with a fungoid ulceration the size of a shilling over it, and a warty excrescence, with a narrow base, close beside. These bleed on the least irritation, and generally emit a most fetid discharge. The tumor is moveable on the muscles, but not to any great extent; it does not affect, nor is it in the least affected by the motions of the limb. He experiences severe smarting and occasional lancinating pains in it, which are so aggravated at night as to prevent him frequently from getting any rest. His general health has been always good.

29th.—To-day the operation for extirpating the disease was practised. A transverse incision, above and below it, included in the

ellipsis the parts to be removed; these were carefully dissected out, together with the fascia covering the muscles, to which they were found connected. Several vessels that bled pretty freely at first were closed by simple pressure with the finger. Thirty drops of laudanum were administered, a wet cloth placed on the wound, and the patient carried to bed.

In the afternoon bleeding came on to so great an extent, that it became necessary to tie two vessels, which, with the application of cold, succeeded in putting an entire stop to the hæmorrhage.

For the first two or three days poultices were applied. A slightly unhealthy appearance of one of the edges was speedily corrected by means of the nitric acid wash, and the limb rolled from below the knee to the thigh, so as to approximate as much as might be the upper and lower lips of the wound.

October 20.—He has not had a bad symptom; the intervening space is now covered with healthy granulations, and there is every reason to expect a speedy and permanent cicatrization.

The tumor removed was very similar to those usually found in the mammae, and when cut into, presented the characters of that fungoid form of malignant disease so well described by Dr. Hodgkin as consisting of a number of little cysts, arising from within a large cyst, and there accumulating themselves until they become so altered and hardened, that the minute structure can with difficulty be recognised; at which period the disease may be known by the bands of glistening fibres shooting irregularly across various parts of it.

Case of Paralysis of the parts supplied by the Portio Dura.

Robert Wheeler, ætat. 6, was admitted into Dorcas' ward, 16th Sept. 1839, under the care of Mr. Key. His mother stated that four years ago, he had "fits;" since which time, however, he had enjoyed good health, till three weeks since, when, on his awaking from sleep, she observed his face to be distorted.

The muscles on the left side of his face were firmly contracted; while the opposite cheek was rotund, and had little power of motion. It does not appear that the patient had any discharge from his ear, or that the portio dura of the seventh pair had received any local cause of paralysis. The paralysis of the muscles has gradually increased, and now affects the buccinator to the angle of the mouth, and right nostril, and partially the orbicularis palpebrarum. There is a puffiness over the right eye-brow. He was apparently in good health at the time of the attack, and he now looks well. His

bowels have been constipated, and are with difficulty excited.

Pil. Hydr. Subm. Co. gr. ijss. omni nocte.

App. Emp. Lyttæ zygomati, et fiat ulcus.
Ol. Ricini, mane sum p r. n.

Oct. 7.—The blister, at the side of his face, has just healed, having been kept open till now. The improvement is very manifest, though the right cheek is still drawn considerably towards the left side when he laughs. He can just direct his muscles to the act of whistling.

Oct. 21.—The deformity of the face is now so slight that paralysis of the right side is only observable in the convulsive action of laughing or sobbing. He has omitted the plummers pill, and is in very good health.

ST. BARTHOLOMEW'S HOSPITAL.

Amputation of the Penis very far back.

PURCHASE WARREN, ætat. 60; admitted into Darker's Ward, October 8th, with an extensive ulceration of the penis of a carcinomatous character. The account he gives of its progress is as follows:—About the month of March, 1827, he perceived a small hard spot on the glans penis, in the exact situation where a chancre had healed about eight years previously. He took mercury for a short time: it slowly increased in size, bearing some resemblance to a small strawberry, but was unattended with pain till about three months back, when, in consequence of its magnitude, a surgeon slit up the prepuce. A slight discharge from the surface of the ulcer had taken place before this, and continued increasing in quantity; the blue pill had been renewed for some time, and he had rubbed in mercurial ointment, and applied black wash: his mouth had been slightly affected. Since the division of the prepuce the ulceration has gradually extended, destroying the glans penis, corpora cavernosa, and urethra, till the mass of disease projects very little beyond the os pubis. Its appearance on admission was,—the surface ragged and fissured, with the edges of the ulceration everted over the body of the penis on each side and below. From this surface, and particularly from a sinus burrowing deep into the mass, a foetid sanies constantly flowed. A slight enlargement of one of the glands in the left groin is felt, but his general appearance is tolerably healthy. He has a small scrotal hernia on the right side, and the whole scrotum is thickened and inflamed on its surface.

The opinions of Messrs. Lawrence and Vincent coincided with that of Mr. Earle, that the prospect of permanent relief from

amputation were uncertain; yet as all agreed that the disease must destroy him if not arrested, Mr. E. decided to perform the operation on Saturday, October 10th.

An incision was commenced at the root of the dorsum of the penis, and carried down on the left side into the scrotum between three and four inches in length; a corresponding incision was made on the opposite side to meet the former, including between them an elliptical portion. Mr. E. then found it necessary to extend this incision completely through the scrotum, and after some dissection, laying bare the tunicae vaginales, the penis and ulcerated tumor being isolated beneath the pubes, a tape was tied firmly round the body of the organ, and a division through the latter made close to it: at this juncture the tape slipped off, but the vessels were notwithstanding secured, and the ends of the ligatures cut off close; the surface of the wound appeared perfectly healthy, as also the posterior extremity of the amputated portion. An elastic gum catheter was passed, the edges of the wound brought together by sutures, and the scrotum approximated as much as possible to the commencement of the incisions. Two or three straps were passed lightly across the line of the wound, and wet lint ordered to be applied constantly. For the first two days considerable irritation and restlessness manifested themselves; the bowels were freely evacuated, and salines with antimony ordered.—On the 12th the wound looked well, and healthy pus oozed from between the straps; they were raised and a poultice applied. He had passed a bad night, his sleep having been disturbed by a troublesome cough. In the evening he was improved in every respect.—14th, Very comfortable.—28th, Going on very well; healthy granulations have filled up the situation of the penis; the thickening of the scrotum has subsided, and the hernial sac is well covered by the right side of the scrotum. The urethra opens into the lower part of the scrotum, and its present orifice is full two inches from the surface. In the progress of the case, it will be interesting to observe what changes occur towards effecting the continuation of the canal. No contraction of the divided extremity of the urethra has taken place at present.

Warren states very decidedly that he had no natural phymosis, or even approach to it.

EDINBURGH ROYAL INFIRMARY.

Cases of diseased Testicle.—Castration.

CASE I.—James Calder, æt. 28, admitted under the care of Mr. Liston, April 30th. Had the left testicle removed twelve months ago, and soon afterwards the right became

enlarged. Its increase was at first slow, but during the last three weeks the gland has enlarged rapidly. A great variety of applications have been employed.

It has now attained considerable size, and is hard at the centre. The surface of the scrotum is irregular, and, on pressing the tumor, purulent matter escapes from two sinuses which extend about an inch into the swelling. The cord appears healthy; urethra sound.

May 1st.—The sinuses have been freely laid open.

May 17th.—Several abscesses have formed in the tumor, and fungi protrude from the former incisions; the patient's health declines, and he is anxious that the testicle should be removed.

May 18th.—Castration was to-day performed. The scrotum surrounding the testicle was consolidated, and the substance of the gland was uniformly diseased, and of a distinctly scrofulous character.

No bad symptom supervened; the wound healed by granulation; the patient recovered strength speedily, and in a short time was dismissed cured.

CASE II.—Thomas McLaren, æt. 25, admitted under the care of Mr. Liston, May 29th. Has had gonorrhœa. About seven years previous to admission, his right testicle was bruised, and became swollen. It continued to enlarge, unattended with pain, till about three years ago; since which there has been no increase of the tumor. During the last three weeks, blisters and mercurial ointment have been alternately applied to the scrotum. The testicle is of the size of a turkey's egg, and is painful on pressure. Urethra sound.

June 6th.—Fluctuation was distinctly felt in the tumor, and, on a small opening being made, a quantity of dark, foetid fluid escaped.

June 8th.—Inflammation has supervened; the scrotum is swollen, and of a livid colour, and the patient has pain in the back, nausea, restlessness, and nocturnal sweats.

June 10th.—As fluctuation was again perceptible, an incision was made, and a considerable quantity of fluid evacuated.

June 14th.—A fungus occupies the wound, and the patient's health declines daily.

June 16th.—The testicle was removed yesterday. The epididymus was enlarged and indurated, and contained pus. The greater portion of the testicle was of its natural appearance, but the tunica vaginalis and albuginea were thickened and adhering to each other. The subcutaneous cellular tissue of the scrotum was infiltrated with lymph and pus. The fungus was connected with the epididymus, in which the disease appeared to have commenced.

June 20th.—An abscess formed over the

cord, and was opened. An incision has been made into the cellular tissue, which had become infiltrated with purulent matter. Healthy discharge from wound, which is cicatrizing. Health good. Was dismissed cured.

CASE III.—David Baird, æt. 31, admitted under the care of Mr. Liston, June 16th. Four years ago had a slight attack of gonorrhœa, and, two years previous to admission, he injured his right testicle while dancing, and the gland became enlarged. It is now extremely hard, and on the lower part of the scrotum there is a small sore, from which a sinus extends apparently into the substance of the gland. The cord appears natural; urethra sound; health good.

June 20th.—The testicle was removed yesterday. It was of a distinctly scrofulous appearance. Considerable hæmorrhage afterwards occurred; an artery was secured, and the wound stuffed with charpie.

June 23d.—There is slight œdema, and considerable redness, extending upwards from the wound; and, on pressure, a quantity of foetid matter escapes. A free incision has been made into the part.

June 24th.—He complains of but little pain, and the discharge from the wound is healthy.

From this date the cure proceeded favourably, the wound healing by granulation.

CASE IV.—James Heatly, admitted under the care of Mr. Liston, July 7th. Had been previously admitted into the Infirmary, affected with disease of testis, and been dismissed at his own request.

His testicle is of nearly the same size as when formerly admitted, but there are several sinuses leading into the gland.

July 10th.—To-day the testicle was removed, much indurated and altered in structure. After the patient had been put to bed, smart hæmorrhage occurred, and several arteries were secured.

July 13th.—The wound looks well. Health and appetite good. This patient also recovered, without the occurrence of any untoward symptom.

CASE V.—W. Angus, admitted under the care of Mr. Liston, August 6th.

Twelve months ago, a swelling appeared on the lower part of left side of scrotum, and gradually increased in size. An opening was made into it, and much blood, with a small quantity of serum, was evacuated. Of late the tumor has enlarged rapidly; its surface is uniform, tense, and elastic; and fluctuation is distinct at its upper part. Veins of scrotum somewhat enlarged. Urethra sound. Complains of slight pain in the back.

June 8th.—To-day a trochar was inserted, but only a few drops of a dark fluid escaped. The testicle was then removed. On account of the very large size of the tumor, the cord was necessarily divided close to the inguinal aperture, and escaped from the fingers of the assistant. The external ring was divided, and the spermatic artery secured. No sponges were employed to arrest the hæmorrhage, *as has been elsewhere erroneously stated.*

The cavity of the tunica vaginalis contained a small quantity of serum, and the tunica albuginea was thickened. The gland was greatly enlarged and indurated, and composed of numerous dense, irregular cysts, containing a glairy fluid, except at its centre and posterior part, where the substance of the tumor was vascular, pulpy, and of the encephaloid structure.

August 9th.—Has slept pretty well. Little pain of wound. Complains of head-ache. Tongue foul; bowels constipated; no pain of abdomen.

Evening.—One scanty stool has been procured by a purgative enema.

August 10th.—Was restless during the night. The wound is painful; emits a thin fetid discharge; the surrounding skin is of a dusky red colour, and presents an obscure sense of fluctuation. An incision was made, and a quantity of fetid pus evacuated. Bowels not moved; tongue foul; pulse rapid; no pain of abdomen.

Habeat statim Pil. Hydrag. gr. v. et Pil. Aloet. gr. x.

Two enemas were administered in the afternoon without effect. In the evening he had ℥ij of croton oil, with a large enema, containing ℥viii. of the same purgative, but no stool was procured.

August 11th.—Had some vomiting during the night, which was checked by an opiate. Towards morning he complained of pain in the epigastrium, and the abdomen was somewhat distended. Leeches were applied to the epigastrium, and he retained 3j. of Epsom salts in his stomach. His pulse suddenly fell; his countenance became anxious, his breathing was very laborious, and the distention of the abdomen had much increased. Took some wine and camphorated emulsion. In the evening he rallied a little, and had a turpentine enema, which procured a dark fetid stool.

August 12th.—This morning had some calomel and opium, and a purgative enema in the evening. His bowels were opened freely, but the distention of the abdomen continued. His pulse became very feeble, vomiting recurred, and could not be controlled by the various remedies employed. He sunk on the 14th.

The friends would not allow the body to be examined.

GLASGOW ROYAL INFIRMARY.

Effects of Iodine on Bronchocele.

JAMES CARRUTHERS, æt. 46, an umbrella-maker; has resided all his life in Glasgow; was admitted by Mr. Cowen on the 18th of February. The anterior and lateral parts of the neck are occupied by a tumor as large as a child's head. It extends from the hyoid bone downwards to the junction of the first rib with the sternum. Towards the left side it passes no further than the outer border of the mastoid muscle, but on the right side beyond this, it has pushed the carotid artery considerably outwards and backwards. The tumor is firm and resisting, and gives little uneasiness, except from impeding respiration. Of late, he has much fallen off in strength. Countenance sallow; has a slight cough; appetite bad; some thirst; bowels lax; pulse 80. It is twenty years since the swelling was first observed, but it had increased so slowly, that, fourteen months ago, it was no larger than a goose's egg. Since then, however, it has increased rapidly. On admission, he was put upon a course of medicine to regulate the stomach and bowels.

25d.—R. Hydriodatis Potassæ 3ss. Ung. Simp. 3j. M utat. 3j. o. nocte.

27th.—He has used the whole of the ointment. The tension and size of the tumor are perceptibly diminished. Has cough, with expectoration; nausea, and uneasiness.

Omit. Unguentum.

28th.—Nausea gone.

Rept. Unguent.

16th March.—The tumor has diminished one-third by measurement. His general health, however, continues to decline; and, at his own request, he is dismissed.

LITERARY INTELLIGENCE.

Early in January will be published, in 8vo. with 14 Lithographic Engravings, *On the Diseases of the Ovaria; including Encysted Dropsy and Malignant Diseases of those Organs.* To which are prefixed, *Physiological Observations on the Structure and Functions of these Parts, in the Human Being and in Animals.* By Edward J. Seymour, M.D. Fellow of the Royal College of Physicians, London; and one of the Physicians to St. George's Hospital.

NOTICE.

Mr. White's paper has been delayed, owing to an accidental circumstance over which we have no control.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

LECTURE VII.

Inflammation from Sympathy.—Disorder of the Digestive Organs.

I HAVE hitherto spoken to you, gentlemen, of inflammation as brought on by causes that act immediately on the affected part; either by such as essentially and necessarily produce that action, in some degree, wherever they are applied, or by such as produce it only in individuals that are predisposed to their agency; and I have mentioned as the most powerful of the circumstances which give a predisposition to inflammatory disease, that state of fulness of habit which is called plethora, and which is brought on by excessive nutrition. Now there are other and numerous cases in which we can observe no direct application made to the affected part; but we discover the existence of disturbance in other quarters, and we find in many cases that the removal of those disturbances brings with it the cure of the inflammation; thus we are led to consider the inflammatory affection as the consequence of the disturbance existing in other parts. The former are cases of what would be called *idiopathic* disease—in which the cause is directly applied; the latter are *sympathetic*, that is, dependent on the previous existence of disease in some other part.

Now I shall just exemplify this sympathetic occurrence of inflammation by certain cases, which will shew you how it takes place. I had a gentleman under my care, who laboured under an affection of the glands of the axilla. He was a young man who had been accustomed to free living, and he did not submit very willingly

to those restraints of diet which his case required. One day, feeling himself low and weak, he thought that a good meal would benefit him, and so he took a hearty dinner and some wine, in opposition to the injunctions that I had laid upon him. He found himself none the worse—perhaps rather the better, and this induced him to repeat the indulgence. On the following day he again took a full meal, and drank some bottled ale with his dinner, and, as he himself acknowledged, about a pint of port wine. This disordered him very much; he passed a bad night, and felt very unwell on the following day; in the course of eight-and-forty hours he became excessively ill indeed—he was hot and very restless, with a full tense pulse, and violent pain in the neighbourhood of the local disease. He sent for me early in the morning, when he presented a specimen of the most violent erysipelas of the skin I ever saw; from the shoulder down to the elbow, the skin was a most vivid red, and beset with those minute vesicles which belong to that kind of inflammation. Here, you will observe, that there was no direct application capable of exciting disease made to the part in which the erysipelas took place: it was a sympathetic effect, so far as the skin went, consequent on a disturbance produced in the digestive organs by imprudence in diet.

I removed in this hospital a loose portion of cartilage from the knee joint of an adult man. At the end of four or five days it appeared that the incision, which had been made into the joint, to remove the loose body, was healed by adhesion: but, in a way that I could not account for, hæmorrhage subsequently took place from the wound, and a layer of coagulated blood was formed; the adhesion that had occurred was separated, and the main object of the operation was frustrated. The consequence was, that an inflammation occurred in the joint, and suppuration taking place, the patient became very ill, and after lingering for some time he died. On opening the body I found inflammation of the

liver and intestines; there were numerous depositions, partly of a purulent nature, and partly of a substance like lymph, in masses, varying from the size of a pea to that of a hazel nut: one such existed in the substance of the brain. In a case of inflammation of the vein of the arm, consequent on bleeding, which was under my care—a case which is technically called phlebitis—there was great distention of one of the knee joints previous to death. On examining the patient afterwards, there was found to have been violent inflammation there, with suppuration of the joint, which was distended with matter, and an immense quantity of coagulable lymph about the muscular fibres of the anterior part of the limb. In another instance of a similar kind, I found inflammation of the pericardium, with fluid in the cavity; and also—a singular appearance—a deposition of pus in the muscular substance of the heart.

This kind of occurrence is not very rare; and there is a paper contained in the 15th volume of the *Medico-Chirurgical Transactions*, stating a great number of cases in which serious inflammatory affections of various internal organs were found in conjunction with severe external inflammations; the internal parts affected were the peritoneum, pleura, and pericardium (three serous membranes), with inflammatory deposits of pus and lymph in the lungs, liver, and spleen; inflammation and suppuration in the cavities of certain joints; and also, in one or two instances, a deposition of pus in the way that I have already mentioned—in the cellular substance, between certain muscles.

Again a patient may have gonorrhoeal inflammation of the conjunctiva without our being able to discern any particular application to the eye; or he may have violent ophthalmia, and this be followed by the sinovial inflammation of the various joints.

These, you observe, are different from the preceding cases, in all of which we could detect the application to the inflamed part of some direct cause of disease. But, in the various instances that I have now recounted, no direct agency can be traced to the part that is the seat of the complaint; and if there is any mode in which we can account for those inflammatory changes in the instances referred to, it is through the indirect and sympathetic influence exerted on the parts by diseases existing in some other organs of the body.

The reciprocal influence which the head and the viscera in the abdomen exert over each other, forms a good illustration of the subject of sympathy, and constitutes, in fact, an inquiry of considerable practical importance. When a person has received a violent injury of the head, nothing is more common than for sickness to ensue, and the contents of the stomach to be ejected by

vomiting; if this does not take place, the patient probably loses his appetite, and becomes costive. If a person in perfect health receive a piece of very bad news or afflicting intelligence, it will entirely destroy the appetite. I have known a gentleman just on the point of sitting down to dinner, in perfect health, receive a piece of news of a distressing kind, and be utterly unable to take a mouthful of food. The state of the stomach is equally capable of exerting an important influence upon the head: thus it is known that worms in the alimentary canal, particularly of a child, are capable of producing convulsions. A state of disorder in the stomach, and other parts of the alimentary canal, in children, will produce disease in the head, bringing on all the external appearances of hydrocephalus. In severe injuries of the head, it has sometimes been found that the liver is the seat of abscess—or rather of the deposition of pus to which I have alluded. On the other hand, the terms *hypochondriasis* and *melancholia*, which are applied to certain states of mental feeling, clearly shew the opinion that has been entertained respecting these affections, as either originating from, or being immediately connected with, the organs contained in the abdomen, particularly the liver. *Hypochondriasis* and *melancholia* are ancient terms, and no doubt were applied to express the connexion between certain states of the liver, or other abdominal viscera, and this condition of mental feeling. In cases of jaundice, every one knows that there is a remarkable degree of languor and dejection.

When you consider the great extent of the digestive apparatus, taking the alimentary canal and the various parts that are subsidiary to it—when you remark the organization of these parts, the copious supply of blood which they receive, and the very important nature of the offices they execute, you will not wonder that they are the seat of a very important set of symptoms. We find, in fact, that nearly all parts of the body are capable of acting sympathetically on the digestive system; and, reciprocally, that these organs are capable of affecting almost all others.

Disturbance of the digestive organs is capable of affecting sympathetically all the other parts, so as to produce inflammation, more or less violent—ulceration, thickening, induration, and various kinds of disorganization. There can be no doubt that to these sources we must refer a considerable portion of those local diseases which, in common language, are said to arise spontaneously—a considerable portion of those diseases, the origin of which cannot be accounted for by the immediate application of any cause. The digestive organs have to perform the important office of preparing

the supply of new materials for the growth and repair of the body. They also remove from the system the residue of alimentary matter after the nutriment has been extracted from it. If healthy supplies of new matter are introduced into the frame, all the animal actions, whether bodily or mental, are carried on with vigour; the body is active, the mind is alert; and a general feeling of health pervades the whole frame. But if the nutritive system is disturbed, if the alimentary canal is loaded with undigested matters, and unhealthy secretions, then materials of disease rather than of health are distributed over the frame; and we cannot wonder that every part of the body should suffer. Every organ may be disturbed, and the mental functions deranged under such circumstances. It is probable, in this point of view, that even character and manners may in some measure be affected by the mode in which the functions of the digestive organs are carried on. This truth seems to have been perceived even by those who have not made medicine a direct or immediate object of study: at all events, the point is handled with a curious mixture of drollery and good sense by Voltaire, in an article in which he has illustrated various philosophic doctrines, and which is entitled "*Ventres Paresseux*"—Costive Bellies. He says that the character and turn of mind in an individual depend very much on the way in which the bowels perform their office; that if a man is costive, his bile is not discharged, but falls back into his blood, and that this renders him choleric. This, to be sure, is not an example of good physiology, but you must understand that this was considered good physiology by medical men at the time that Voltaire wrote. He mentions that Cardinal Richelieu laboured under inward piles, which obstructed the lower bowels, and produced constipation. Owing to this, says he, the Cardinal became cruel; and thus he accounts for the sanguinary disposition occasionally evinced by this eminent statesman. He says that the Queen Anne of Austria was accustomed to call him by the name "*cul pourri*," which we cannot translate into decent English. Voltaire adds, that "if a person should have to ask a favour of a minister, or of his secretary, or of his kept mistress, he should endeavour by all means to ascertain whether they go regularly to the close-stool. If possible, he should select for the time of preferring a request the period immediately after the individual has had a comfortable evacuation, for it is a remarkably propitious moment: it is one of the *mollis faudi temporu*, which ought always to be seized, one in which a man is in good humour with himself and all around him.

Now since disorder of the digestive organs

is sympathetically a cause of many local effects, and since the efforts for their cure will depend materially upon our success in discovering the cause, and in applying suitable remedies, it is necessary to inquire a little more particularly into the mode in which such derangement takes place, and into the circumstances which denote its existence.

We find, in the first place, that all kinds of serious external injuries are capable of producing sympathetic disturbance in various parts of the alimentary canal; and that pain and tenderness in the hypogastric region, thirst, diminished appetite, costiveness, and increased frequency of pulse, with heat of skin, very remarkably, attend such accidents. Thus they form an assembly of symptoms, constituting a kind of fever; these circumstances being, for the greater part, immediately referable to the disorder I have just mentioned. We find, also, that every considerable local disease, as well as external injury, is capable of acting sympathetically on those organs. A knowledge of the disorder which is produced is a considerable step towards the cure of the injury or primary disease itself. However, the most frequent cause of disorder of the digestive organs is, unquestionably, excess of nutrition, which I have already had occasion to allude to as being the immediate source of that state of plethora, which constitutes the predisposition to local inflammation. The excessive supply which is introduced into the system, under such circumstances, is attended, in the first instance, as I have already observed, with a more vigorous exertion of the various organs of the body; there is, in fact, an actual increase of the various functions, producing what seems for a time to be a remarkably healthy state. We soon see, however, that this is changed into a condition bordering on disease; that the individual so circumstanced has a full and strong pulse, heat of skin, and headache; and that perspirations are easily induced by exertion. He has a white tongue; and, in fact, he passes into a state closely allied to disease, although it is still called health. This condition of plethora, or an unnaturally full state of the system, may, as I mentioned, be regarded as the first step in a deviation from the healthy state; it is a condition in which disease will easily be induced, and in which, when induced, it assumes a very active inflammatory character. It is pure, simple, or common inflammation which occurs under such circumstances; that is, inflammation arising from the excess of nutrition in an individual who is otherwise healthy. Now, if the same cause continue to act—that is, if to the system, which is already overloaded, fresh supplies are continually added, then the condition of the organs begins to be altered; they are unable to dispose of the matter thus brought in;

they get out of order; and the individual soon passes into an unhealthy condition. You will naturally expect that the functions of the stomach into which the food is taken, should be immediately deranged; in fact, digestion is first impaired under such circumstances: and the actions of the absorbent, the nervous, the chylopoietic, and the vascular systems, are subsequently disturbed. The fecal and urinary discharges become deranged in various degrees, and you have symptoms proving the impaired performance of these actions, by which the residue of the alimentary matter ought to be removed from the system. You find, perhaps, a foul and loaded state of the tongue; not unfrequently a kind of voracious appetite; costiveness; and the motions, when obtained, dark and unnatural in their appearance. The urine is deficient in quantity, high coloured, and turbid; the skin is sallow, harsh, and dry; and occasionally even an unpleasant sort of perspiration is produced.

Now in the first of these two states there is plethora from an excess of nutrition,—an overfulness, from the effect of an improper quantity of aliment being taken into the body. In the other case the principal source of disease is a defect of excretion. The second condition is beyond a state of mere plethora—it is plethora, with defective secretion added to it. These terms may serve, in a general way, to characterize the two conditions I have just alluded to—plethora from excessive nutrition, and plethora with defective excretion. These states have been spoken of by Dr. Barlow, who endeavours to investigate what appears to me to be an important point—namely, the mode in which health passes into disease. He has attempted to trace the state which intervenes between health and the development of disease in its obvious and recognizable form; and it must be very clear that in order to understand the way in which disease is produced, and may be recognized, such investigations are of great importance. Dr. Barlow has published his views in a series of papers, which you will find in the 9th and 10th volumes of the Edinburgh Medical Journal; and he has also published them partly in an essay on the Bath waters, together with some remarks on the physiology and pathology of the human frame, printed at Bath in 1822. It was only lately that I had an opportunity of seeing the writings of Dr. Barlow; and I was much pleased to find, in perusing them, that there was a coincidence between his views and those I myself had been led to entertain upon the same subject. I find that Dr. Barlow and I have not only taken up the same views, but what is still more singular, we have expressed ourselves in nearly the same language:—I was pleased to find that my own notions

were confirmed by the sanction of so intelligent an observer. I think that Dr. Barlow would confer an immense service upon the profession if he were to put into one volume the matter which is scattered through the works that I have referred to.

It is necessary, however, to go a little more minutely into the symptoms of the condition I have just mentioned, more especially as they appear in the particular parts of the digestive system; but it will not be requisite to detain you at great length on the subject.

In the stomach we observe, under the circumstances alluded to, that certain uneasy sensations are produced; after taking food, a sense of weight, and other unpleasant effects, are often experienced. We find, after this, a defect of appetite, with flatulence. In other cases an unnatural desire for food comes on, and, although what is taken is not properly digested, yet there is a constant desire or craving for food, that leads the individual to add to the load by which the organs are already oppressed. In the intestines we notice an irregular performance of their functions—very commonly a state of costiveness; and this is succeeded by, or perhaps alternates with, diarrhoea. Sometimes the intestines contain an accumulation of feculent matter, so that a large quantity is lodged in them, and continues there for a considerable length of time. This will occur although the patient has regular motions, and it is by no means uncommon for a considerable quantity of matter to remain in the alimentary canal notwithstanding.

When we regard the size of the liver; when we look at its complicated structure; when we see the great peculiarity by which the blood that has circulated through the abdominal viscera,—the venous blood is conveyed so as to circulate again through the liver; we naturally expect to find that some purpose of great consequence in the animal economy is answered by this organ: but hitherto we cannot tell what it is, nor can it be said that we have discovered in the liver any purposes of importance that seem to explain the design of its peculiar organization. It has been discovered that the colour of the fecal evacuations depends on the admixture of bile, and therefore it has been imagined that the appearance of the motions may be regarded as a criterion whether the liver be in a healthy state or not. To a certain extent these notions may be correct, for we see, when the passage of bile into the alimentary canal is stopped, as happens in some cases, that the fecal matter has a whitish grey appearance, totally different from that peculiar brown colour which belongs to it in the healthy condition. The admixture of bile, however, is not the only circumstance which is to be regarded in considering the colour of the

evacuations; the peculiar nature of the food very often has a marked effect in this respect. A particular substance taken into the stomach will produce a corresponding appearance; it is well known, for instance, that steel medicines make the stools black, and that taking a quantity of stewed spinach will make them green. There can be no doubt, when we consider that the whole tract of the alimentary canal is a secreting surface, that the secretion produced by it will vary much under different circumstances. The nature and quality of this secretion, as well as of the bile, must affect the colour and appearance of the motions.

The tongue seldom presents a natural appearance when the alimentary canal is disturbed; a foul loaded state of the organ, its being covered by a kind of nasty clammy deposit, is an uniform sign that the stomach is in an unhealthy state. There are varieties in the appearance of the tongue: it does not always exhibit the same character; frequently, in those disturbances of the stomach and alimentary canal which are of long standing, it is of a yellowish brown appearance, something like buff. The white state of the tongue is not, in my opinion, to be particularly regarded as indicating disorder in the stomach. We see the tongue white, not in consequence of its being covered by any deposit or secretion, but as if from the substance of the tongue itself being rendered white. This is observed in cases either of plethora, when passing almost into a condition of disease, or in cases of active inflammatory disturbance, and is an indication of those states rather than of particular disturbance of the stomach. It is a tolerably unerring criterion of the existence of inflammation, and it may be considered as a sign that we ought to bleed those individuals in whom it is noticed. Whenever the functions of the stomach, liver, and alimentary canal are impaired, you must carefully examine into the state of the urine; to find if it be properly secreted, or if it be altered in quantity or in quality. It is the office of the kidneys to separate from the blood a considerable part of what we call the residue of the alimentary matter—to remove a considerable part of the food which has been carried into the lacteals, but which is not wanted for the purposes of nutrition. If the quantity and quality carried to the lacteals be unhealthy, you will have changes in the state of the urinary system: thus the urine is thick, muddy, or turbid, and a variety of changes take place which have lately been made the subject of curious chemical investigation, but we may at present take the alteration in the urine merely as an indication of the unhealthy performance of the digestive functions.

In concurrence with these circumstances,

you will find the state of the skin more or less deviating from a natural condition. There is a peculiar dingy aspect of the complexion, a sallowness of countenance, a dryness and harshness of the surface of the body generally, which form a striking contrast, both in respect to the feeling when touched, and the appearance to the eye, with the naturally soft, light reddish, and slightly moist surface of the skin. That the state of the skin is an important criterion respecting the health of the animal, is a fact known to those that take care of horses. An expert groom will tell you whether the horse be in good condition by the state of his hide; and the skin of the human body affords an equally good criterion of the state of the man.

Such are the various circumstances that point out to us the existence of those disturbances, or diseases, in the alimentary canal, or in the digestive organs taken generally, which are the source of a great variety of those local inflammations which we cannot trace to any immediate cause—to any direct agency applied to the affected part.

You will observe that the condition I have been speaking of may be regarded in two lights. You may view the matter as a general condition of plethora of the system, or you may particularly attend to it as indicating disturbance of the digestive organs: the one is more general, the other rather a more partial view of the same phenomenon. I need hardly observe that Mr. Abernethy has particularly directed his attention to the evidence of disturbance afforded by the digestive organs. Without speaking pointedly of the state of plethora of the system, he has described at considerable length the symptoms of disturbance, the mode in which it acts in producing local disease, and the means by which it may be most successfully combated. Perhaps the views which have been given by Dr. Barlow might be advantageously combined with those of Mr. Abernethy; they would, when united together, form a more complete portrait of this state of the system than if you took either of them separately.

No doubt other observers must have been led to take into their view circumstances which are really so obvious and of such common occurrence. Dr. Hamilton, of Edinburgh, in a work entitled *Observations on the Utility of Purgative Medicines*, recommends treatment essentially similar to that advised by Mr. Abernethy, but in which he has taken up the subject entirely in a practical point of view. He has not entered into a pathological consideration of the question; he has not attempted to shew the mode in which the overloading of the alimentary canal takes place, nor in what way it produces the disease, that he proposes to treat by purgatives; but has limited himself to the fact, that, in a great number of cases,

much benefit may be conferred by active purgation. In a neighbouring country (France) the attention of the medical profession has been powerfully directed to this part of the subject by an individual of great talent, who perhaps may, in some measure, have carried his views beyond what we should deem their just limits. He ascribes to the digestive organs the production of fevers. I allude to Broussais, the author of the "*Examen de la Doctrine Medicale*." He refers to diseases of the mucous membrane of the stomach a great share of all the diseases that occur in the human body. At all events, we find in his writings a considerable mass of evidence, shewing more particularly that to the active disturbance of the digestive organs are to be referred many of the diseases which are met with in France, as evidenced by examination after death, in numerous cases; a part of the subject for which opportunities equally ample have not existed in this country. I should consider, therefore, that the concurrent opinions of Dr. Barlow, Mr. Abernethy, Dr. Hamilton, and M. Broussais, all tend immediately to support each other. We cannot, perhaps, say that the opinions of any of these individuals are to be adopted to the full extent, but no doubt there is a great deal of truth in the statements of each, in as much as they arrive nearly at the same point, and this, too, by different modes of investigation. Their concurrence, so far as they go together, is a strong argument in proof of what they have deduced, and of the accuracy of their views of disease, both practical and pathological.

CLINICAL LECTURE
ON
VESICO-VAGINAL FISTULA.

By H. EARLE, Esq. F.R.S.

To the Editor of the London Medical Gazette.

SIR,

IN reply to your letter on the subject of my clinical lecture on vesico-vaginal fistula, I beg to assure you that I have no hesitation in complying with your request, if you think it of sufficient importance to interest the medical public; and have the honour to be, Sir,

Your most obedient servant,

HENRY EARLE:

George-Street, Nov. 8, 1829.

GENTLEMEN,

I wish to draw your attention to the very distressing case of Jane Latimer,

in Sitwell's ward, who was admitted in September, with a very large communication between the bladder and vagina. She states that she is 27 years old; that she had had two children. Her first labour occurred two years ago, when, after remaining three days and nights in parturition, she was delivered with the assistance of instruments, and the child was lost. She recovered perfectly from this, and again became pregnant. Her second labour occurred about six months since, and in this she lingered for three days and nights, when she gave birth to a still-born child, with the unassisted efforts of nature. In this latter labour she was attended by a female, and she affirms that no urine passed during the whole time. Some time after the child was born the bladder gave way, and a very large quantity of urine escaped per vaginam. She recovered from her confinement very well, but the urine has continued constantly to come away through the false passage. Her general health is unimpaired, and she suffers much less from excoriation than is usually the case. On a careful examination, I ascertained that there was no deformity of the pelvis to account for the difficulty experienced in her labours. On examination per vaginam, a large opening, with a lunated edge, could be felt, through which the finger could be introduced into the cavity of the bladder, at about an inch and a half from the vesical extremity of the urethra. On tracing the boundaries of the bladder, the upper edge of the opening towards the uterus could not be distinguished. The soft mucous lining of the bladder protruded through the opening, and was continued on to the neck of the uterus. Such was the impression conveyed to the finger, and subsequent examinations with the speculum proved it to be correct. In these latter examinations the increased vascularity and more villous surface of the bladder could be very easily distinguished from the lining of the vagina, which was much less vascular, and thrown into folds. The exposed lining of the bladder was infinitely less sensible than I have ever found it in other cases; and there was no injury done to the vagina beyond that portion which had been involved in the destruction of the bladder. In this respect also this case differs much from most others, in which there are generally firm cicatrised bands extending

across the vagina in different directions, and much diminishing that cavity. The opening in the bladder extended laterally above an inch and a half.

I have been induced to select this case particularly for your consideration, because most of you will probably be called upon to practice midwifery, and much important information and useful precaution may be drawn from the history which I have presented to you. In the first place you will have remarked that although the first labour was equally lingering with the second, that she was safely delivered with the assistance of instruments, without any untoward accident; whilst in the second, nature was left to perform her task without assistance, the consequence of which was the unfortunate occurrence which has reduced her to her present miserable condition, in which she must feel her life a loathsome burthen to herself and others.

It forms no part of my duty to instruct you when, and under what circumstances, you are to employ instruments and assist the delivery of your patients; you will, no doubt, receive ample instructions on this subject from your able midwifery professor. I may, however, be allowed to say, that, contrasting the results of the two labours, it would appear far better to employ instruments, than to suffer the head of the child to remain so long in its passage as to endanger the vitality of the parts on which it rested. But it may be said, that this lamentable accident need not have occurred, if proper precautions had been taken to empty the bladder with the catheter during parturition; and here I shall trespass so far on the province of your obstetric teacher, as to impress most strongly upon your minds the vast importance of attending to this part of your duty in all cases of lingering labour. You must not be satisfied with the report of the nurse or of the patient that water has passed, but you must ascertain that point for yourselves. It has fallen to my lot to witness, or to be consulted about many cases of this description: the present case makes the twenty-first which has come within my knowledge. This fact alone is sufficient to impress you with the importance of the subject, and the necessity for you to employ all vigilance to prevent its occurrence. In all these cases, where I have been able

to ascertain the particulars, the patients have either been suffered to remain too long in labour, or the bladders have been allowed to remain unemptied during parturition.

And here I would observe, that you should be provided with a catheter, smaller, and much longer than the one commonly employed for the female bladder. It often happens in these cases, that when the child's head descends, the bladder is pushed upwards above the pubis, and the urethra is much extended: in such cases you would fail to reach the cavity of the bladder with a common catheter, and you would probably be obliged to employ a small elastic gum male catheter to effect your object. A remarkable illustration, in proof of this, occurred in this hospital in the course of last summer: a young female, of 17 years of age, was admitted in even a worse state than the present patient, all the parts being in so painful and excoriated a state that she could scarcely allow an examination, and would not permit any attempts being made for her relief. In this case the medical gentleman who attended, at three several intervals of time introduced the catheter, without drawing off a single drop of urine, and none flowed naturally. There can be no reasonable doubt that the catheter never reached the cavity of the bladder, as urine flowed in abundance after delivery.

There are some other points connected with the nature and history of these cases on which I shall detain you a short time, as it may be of much importance for you to be aware of them; I shall then conclude with some observations on the means best calculated to afford relief.

I have already stated to you that in all the instances which I have investigated, this destruction of a portion of the vagina and bladder has been the consequence of the undue pressure of the head of the child, or the distended state of the bladder. I ought, however, to have made one exception, in which the fistulous opening was clearly referable to the unskilful employment of the crochet; in which, in fact, the bladder was lacerated. Now, as it may happen that in cases of this description, where instruments have been employed, questions may arise, and even be carried into courts of justice; whether the blad-

der has been ruptured by the injurious or rough employment of instruments, it will be well to offer a few observations, which will enable you to distinguish between cases of ruptured or lacerated bladder, and cases of ulcerated or sloughing bladder. The distinction is simple, but quite conclusive. In all cases of lacerated bladder, the urine would flow through the aperture at the time of the accident, and continue to do so from the immediate receipt of the injury. When, on the other hand, a portion of the vagina and bladder has perished from pressure, the patient will pass her urine for some days after her delivery through the natural passage; her discharges will be very fetid and offensive; and after the lapse of two, three, or five days, the sloughs will begin to loosen, and urine will flow through the vagina: when the sloughs are detached, they will be found thickly encrusted with calculous matter, which in some instances has led to the supposition of the pre-existence of a calculus in the bladder, and that the mischief has been caused by the bladder being compressed between the calculus and the head of the child; this, however, is clearly an erroneous opinion. It arises from the salts of the urine being deposited upon the sloughy mucous coat of the bladder. The moment any part loses its vitality, it becomes and acts as a foreign body, and forms a nucleus for the deposit of the salts of the urine. This view of the subject is further confirmed by the fact that the same incrustations are found on the sloughy portions of the membrane of the vagina, which are detached after the partial separation of the bladder has taken place. These calculous incrustations tend greatly to aggravate the sufferings of the patient.

It remains for me to speak of what remedial means we have in our power in these most distressing cases; and here I must make the humiliating confession that, in the majority of cases, little can be done to obtain a cure, although much may be effected to contribute to the patient's comfort. In calculating the probability of success from any curative operation, much must depend on the situation and extent of the injury. When that portion of the bladder has perished which is situated in the triangular space included between the termination of the ureters

and the commencement of the urethra, I fear no rational grounds of hope can be entertained of success, as the urine will flow through the fistulous opening as rapidly as it is secreted, and will effectually interrupt any healing process. Again, when the opening is in this situation, there would be danger of cutting across the termination of the ureters in endeavouring to remove the callous edges of the opening. This danger, and the difficulty of treating such a case, will be better understood by referring you to this preparation, and this drawing, which was taken from it when in a recent state. The subject from whom this preparation was removed was a young Irish woman, who came into the hospital in an advanced stage of acute peritonitis, and died the following day. She had been delivered one month, and had been attended by a drunken midwife, who suffered her to linger many days in labour, administering from time to time her favourite cordial to the patient and herself. In this case you will perceive that nearly the whole portion of bladder between the ureters and urethra has sloughed away. The bristles which are introduced into the ureters are seen immediately at the edges of the opening. It would have been quite impossible in this case to have effected any thing by operation. In this case you will likewise see the hernia of the mucous lining of the bladder, which is turned upwards, and is united to the neck of the uterus, just as I have described to be the case in the patient at present in the hospital. In the drawing the comparative vascularity, and other characteristics of the lining of the bladder and vagina, are clearly marked. In this case, also, you will observe that the mouth of the uterus has been closed by the inflammation which was produced. The uterus was distended with menstrual fluid, and it is probable that the peritonitis was excited by this obstruction, as there were much greater traces of inflammation over the pelvic viscera than in other parts of the cavity of the peritoneum. This circumstance reminds me that I had omitted to mention that in the case now in the hospital the patient has not menstruated since her confinement; but I have ascertained that there is no obstruction in the mouth of the uterus, by introducing a full sized bougie into its cavity. When the open-

ing in the bladder is situated nearer the fundus beyond, or rather higher than the ureters, there is a far better prospect of success, as in that case there will be a cavity to receive the urine, which may be allowed to flow off through a short catheter as rapidly as it is secreted. The probability of affording relief even in such a case, must, however, depend on the extent of the opening, and the degree of eversion or hernia of the bladder; and here I would observe that this eversion of the bladder appears to depend on the greater destruction of the coats of the vagina in proportion to those of the bladder. In the process of cicatrization, where there has been a large slough of the vagina, the bladder is drawn out to supply its place, and becomes firmly united and continuous with the surrounding vagina. It must be confessed, that under the most favourable circumstances, these cases present the greatest obstacles, and are certainly the most difficult that occur in surgery. I do not mention this to discourage you from making attempts to relieve patients suffering under this great calamity; on the contrary, I would strongly urge you not to abandon them, and not to be deterred by many failures. I have succeeded in perfectly restoring three such cases; in one of which I performed upwards of thirty operations before success crowned my efforts. [Here Mr. Earle gave a short account of this case, and the means he employed to effect his object.]

The sources of difficulty attending these cases are manifold. One of them has been already alluded to—namely, the continual flow of urine, and the vicinity of the termination of the ureters. Another is the very narrow space for performing any operation, often rendered more narrow by preternatural contractions, and firm cicatrized bands. A third source of difficulty in attempting any operation arises from the exquisite sensibility of the exposed mucous membrane of the bladder: next, the moist, unresisting, elastic surface, eludes the impression of any cutting instrument, the edge of which is almost immediately blunted by the action of the urine. Even when these are surmounted by perseverance, and a modification of different instruments, such is the influence exerted over the pelvic viscera by the slightest movements of the viscera of the abdomen, by the action of the

abdominal muscles and the diaphragm, that the adaptation of the denuded surface is often frustrated, and even the sutures forcibly torn away, by a single effort to cough or sneeze. In one most interesting case, which occurred in the person of a medical man's wife, where the whole urethra and neck of the bladder had sloughed away, after I had succeeded in forming a new urethra, I was repeatedly frustrated in my attempts to unite the surfaces by the occurrence of a cough or sneeze, or some action of the respiratory muscles, which was directly communicated to the bladder and pelvic viscera through the medium of the viscera of the abdomen. But supposing, that by great care and perseverance, and the perfect quietude of the patient, all the obstacles already enumerated have been overcome, and the newly paired edges of the opening have been brought accurately in contact, and firmly secured, yet you will have another source of difficulty, which may render all your efforts abortive, and this I have reserved for the last, as it is unquestionably one of the greatest magnitude.

You will have to contend with a positive law in nature which is directly opposed to the union of mucous surfaces by adhesive inflammation. You are, no doubt, aware of the salutary laws which regulate the functions of these membranes in health and disease, and are sensible of the importance of preserving all canals with external outlets free from those adhesions which so constantly occur in inflammatory affections of the serous membranes: and it is with this powerful and wise ordination that you will have to encounter, in your attempts to restore the ravages effected by sloughing or ulceration of the vagina and bladder. I need say no more to convince you of the difficulty of the undertaking; but, at the same time, I entreat you not to despair, and not to abandon your patients without some efforts to relieve them.

It remains for me yet to state what curative and what palliative means we possess in these cases. When the opening is not situated between the urethra and ureters, or in the neighbourhood of the latter tubes; when it is not of great magnitude, and when there is not much hernia of the bladder, you may attempt to remove the callous edges, and unite them by the assistance of sutures. You will be much facilitated in this opera-

tion by previously dilating the urethra sufficiently to admit the fore-finger of the left hand; by which you will be enabled to draw down the bladder and to afford a support and resistance in removing the edges. The instruments best adapted for this purpose, are very narrow double-edged scalpels, or lancets, with which you may pierce through the membranes and cut your way outwards. These should only cut a short distance from the extremity. It will be better to commence at the extreme edges of the opening, and not to attempt to effect too much at any one operation. By several operations you will gradually diminish the aperture, but by attempting too much you will be foiled altogether. To enable you to convey a suture through the edges, to hold them in contact, it will be necessary to employ *port-aiguilles*, with grooves which will hold a short triangular glover's needle at different angles, and with slides adapted for holding or letting loose the needle. The following is the mode in which I have employed this:—An armed needle should be fixed at the angle most convenient for piercing the denuded edges of the wound, which should be directed by the finger, and carried through the two edges. The point should be received by the other *port-aiguilles*, and the slide pushed up to fix it. The slide of the first should then be drawn down, which will leave the needle in the grasp of the second, by which it may be drawn through with its thread attached. To effect this in so narrow a space as the vagina is often most difficult, and requires much patience and dexterity. The ligature should be drawn tight, and the ends cut off. I have also employed short hare-lip pins, and the twisted suture; but these are still more difficult to pass, and cause much more irritation. In those cases which, from the situation of the opening, or its magnitude, no curative means can be attempted, a well-adapted truss, with an elastic gum pad, will often enable the patient to retain a considerable quantity of water, and to enjoy comparative comfort.

[Mr. Earle concluded his lecture by exhibiting the instruments he employed, and the sort of truss which he had found best adapted for these cases; one of which, he stated, he was about to have made for the patient now in the hospital, as he despaired of effecting

any more permanent cure, in consequence of the size of the opening and the great protrusion of the lining of the bladder.]

ADDRESS OF DR. BADHAM,

Professor of Medicine in the University of Glasgow;

On the Annual Distribution of Prizes for 1829.

NOTWITHSTANDING several severe impediments of a private nature, I could not suffer a second solemnity of this kind to pass without rising in my place, in order that the class which I have the honour to instruct might not be unrepresented on a great public occasion; in order, too, that individual merit might not be deprived of its public testimony, nor my intention farther postponed of saying a few words dictated by the interest I take in the students of medicine as a body, and in the rank I conceive them entitled to hold in a system of general education. That in this country, sir, meaning Britain at large, (for my remarks are by no means applied to Glasgow in particular) the whole course of public patronage and encouragement is applied to promote excellence in classical pursuits, is an undoubted, and, I think, an unfortunate fact; for though I am a friend most decidedly to all the pursuits of learning, and the inducements to excellence in them, I cannot but desire that they were not quite so *exclusive*—as if there were but *one* paramount object upon earth, the value of which, let it be what it may to the individual, is (I have the confidence to think and the courage to say it) so inconsiderable to the public, *compared with others*, that the *exclusive* countenance and protection afforded to it *does* appear sufficiently remarkable. For, estimate these studies, and their results, at the highest price, they are surely *still but subordinate*; not the column which *sustains the weight of the building*, but the capital only—not the shaft, but merely an embellishment which contributes its graceful yet not indispensable ornament, and which leaves the grandeur, the stability, the eternity, of the construction, to rest upon its proper foundation. As to medicine, it is my object to maintain that although she may often be disco-

vered in intimate relation with classical accomplishments, she has an *innate majesty* and a higher purpose, not indeed incompatible with, but completely *independent of them*; that the studies she peculiarly enjoins may challenge comparison in their *tendency* and *effects* with any that have usurped to themselves the over-fond and exclusive admiration of mankind. For if it *be difficult*, as I apprehend it is, to refuse a somewhat higher rank to science than to learning, it seems *impossible to do so* in those cases where great public purposes are contemplated and attained. Even the architect who asserted that he would suspend the Pantheon of Agrippa in the air, and effected that gigantic enterprise in the construction of the Cupola of St. Peter's, has left a far prouder evidence of his existence than the scholars of his day; and medicine is as far in excellence superior to *unapplied*, or *inapplicable literature*, as a purpose almost divine, accomplished by profound contemplation, and at the expense of personal ease, rises above the narrow objects of elegant and perhaps dangerous refinement, which, be it remembered, are selfish purposes at best. Her purpose and study have ever been the same; but when I add that the power of *executing* that purpose has in our times become as strikingly superior through the advancement of science, as the progress of a vessel impelled by its engine against the tide is superior to that of a barge on the towing path of a canal; or as the flight of a Congreve rocket is a more sublime instrument of dispersion and dismay, than the herd of oxen driven by night into the camp of the Roman Consul with torches tied to their horns, I suppose I may venture to claim for the student of medicine that he be at least equally welcomed, encouraged, and applauded, with the fabricator of faultless pentameters and immaculate iambics. And if, after all, injustice or pre-occupation shall deny him his just and well-earned place among his fellows, let him be consoled, and contentedly wear the not ignoble wreath which designated the man that had saved the life of a fellow-citizen—a full indemnity for that precarious and perfidious laurel of which the poisonous *emanation* seems at times to affect the brain under the brow which it adorns. Not that I am obliged to renounce for medicine the vanities of literature. I

have not forgotten that Greek letters were first introduced into Britain, and personally taught at Oxford by *Linacre*, the friend of Erasmus, the pupil of Chalcondylas, and the founder and president of our College in the reign of Henry VIII.; I have not forgotten, and I would not have the classical student forget, in his admiration of the phrenzy of Orestes or the sorrows of Electra, that he owes the first important editions of two of the Greek Tragedians to Dr. Musgrave; that his *Constantine*, the most copious and probably the best of the Greek Lexicographers, was a *physician*; that the learning and wit of Rabelais, the acuteness of Locke, the copious eloquence and various accomplishments of Haller, Gessner, and Zimmerman, were enlisted in the cause of medicine; that the Latinity and learning of Sydenham, Morton, Friend, Mead, Baker, Heberden, and Ash; the science of Woolaston, and the poetry of Garth, Goldsmith, Armstrong, and Akenside, are all our own, and have been connected in the most of these instances, with high professional eminence. If I claim, then, for medicine a separate, an independent, and a nobler existence, it is that I deem her temple *strong* enough to stand without the support of any buttress, and *beautiful* enough to dispense with the ornature of any parasitical vegetation.

Sir, I have said enough, perhaps more than enough, to shew that students of medicine are entitled to the consideration of studies directed to the highest purposes—if, indeed, the contemplation of those prospective contrivances, and harmonies of design in the structure of man and the material world, which inspired Paley with his eloquent theology, be allowed to be equal in importance to the study of the harmony and prosody of languages. But not to dwell on the course of painful and toilsome, yet liberalising and elevating studies which our profession exacts, nor on its ordinary exercise involving consequences far more hazardous to our own security and comfort than the studies themselves, I would ask the scholar (and in *no spirit of depreciation of pursuits which I admire—for my object is not to depreciate letters, but to assert the rank of medicine*) what sacrifices of inclination or repose he is required to make to mankind in return

for their blind admiration. Is HE called upon, at the slightest suggestion of duty, to tread the *tainted floor of the pest house*, or inspire the suspected atmosphere of the Lazaretto? Is HE enjoined to follow with his foot-steps, as he *cannot but follow* with his applause, the sublime devotion of those young and generous heroes who quitted, *without* the call of duty, the most fascinating capital in Europe, to explore, under a sky in which the vultures were hovering, the character of a new and ferocious epidemic, and to carry the succours of humanity to the beauty of Barcelona or the valour of Gibraltar?

I will scarcely condescend, sir, to appeal to personal or domestic considerations which so readily offer themselves, to my argument, or state what every one must know, that the possession of superior *comeliness*, as well as improved *strength* and augmented *security*, through whole communities—throughout society—are the unspeakable gifts of the art of medicine. I will scarcely desire my fellow-citizens to turn to their own homes, and amidst the ostentatious claims of classical attainments, pressed beyond their just value, by an admiration not always sincere, bid them remember *whence* they derived their consolation in affliction, in their own persons or the persons of those they love. How often, when the hot and chafed blood was dashed against its bulwarks, like the tide of some disturbed Æstuary, and the once calm and placid respiration had become an hurricane, has the *white star* of medicine (like the constellation of the Dioscuri to the ancient mariner) risen upon your dwelling, the harbinger of returning security, and the pacificatrix of the storm?

*Defuit saxis agitata humor
Concidunt verti, fugiuntque nubes
Et minax, quod sic voluere, ponto
Unda recumbit.*

LITHOTRITY—AN ENGLISH DISCOVERY.

By JOHN ELDERTON, Northampton,
Memb. Coll. Surgeons, London.

To the Editor of the London Medical Gazette.

SIR,

THE attention of the medical profession has been called, of late, to the perusal of some papers relating to the intro-

duction of lithotry; a process the writers appear to treat of as emanating from our professional brethren on the Continent. It is by no means my intention to enter into any elaborate discussion, but merely to demonstrate the priority of invention with the English, and to conclude with a few general remarks on the employment of the apparatus.

For many years I have occasionally submitted to some professional gentlemen in town various attempted improvements, both in surgical operations and instruments; and that I may not be thought to misrepresent, I beg to observe, I shall make no allusions but to what I can verify by letters in my possession.

The possibility of constructing an instrument to supersede occasionally the operation of lithotomy, was an idea that struck me when early initiated into the profession; and, to accomplish the project, an artizan of the name of Chapman (employed by the Governors of the Northampton Infirmary, where I was then an apprentice,) was employed to construct the model. This apparatus I now possess, and a moment's inspection bespeaks the following views in the contriver; namely, forceps to hold the stone, effected by the longitudinal division of the curved part of a sound or catheter, tempered to expand, and made to close through the medium of a stilette passing down the instrument. To pulverize the stone, when not susceptible of comminution through the pressure of the forceps, a second stilette is passed down the instrument, having a construction for the employment of either rasps or drills.

As my object is merely to substantiate the originality of the invention, I shall not enter into a detail of other properties this model would be found, on examination, to have aimed at attaining: but, to establish the truth of the above particulars, I refer the reader to the accompanying statement, made on oath by Mr. Samuel Humfrays, surgeon, wherein it will be seen the lithonriptor was planned during our contemporary apprenticeship, and prior to the summer of 1813, when I quitted the Infirmary to pursue my studies in town.

From the above-mentioned period of my visiting London, to the close of the year 1816, when I was engaged as a professional assistant to an emi-

ment surgeon, of the name of Hodson, of Lewes, nothing had been farther transacted in perfecting the lithontrip-tor, until the possibility of yet improving the instrument again attracted my attention, and gave origin to a series of diagrams, from which a person named Gurr, at Lewes, in May 1817, constructed the apparatus that afforded the epistolary correspondence referred to in the Letters Nos. 3, 4, and 7.

Having been appointed to the office of house-surgeon to the Northampton General Infirmary, soon after quitting Lewes, in June 1817, I engaged, late in the same year, a watch-maker named Whitmore, now living at Northampton, to perfect my views; and, accordingly, the instrument was made, an account of which I published in the *Edinburgh Medical and Surgical Journal* for April, 1819.

It might be here observed, that the instrument made by Gurr, of Lewes, was publicly exhibited when passing through London in the summer of 1817; as was that made by Whitmore, in the close of the same year, shewn to many eminent surgeons in town, for their opinion, in 1818. For the correctness of these statements I refer the reader to the perusal of the Letters and Extracts annexed; and as the individuals to whom references are made (with the exception of Mr. Roberts, late surgeon at Lewes) may be personally appealed to, the claim, as regards priority of invention, is *conclusive*, and when coupled with the public exhibition of the apparatus at St. George's Hospital, in London, in the summer of 1817, might possibly afford some clue to the singular coincidence of the instrument being said to have been invented in France shortly after.

The following are the references selected from many other letters, confirming the history of the invention, as advanced above; and should the profession express surprise that I did not put the instrument to the test of trial, I plead as a reason the influence of opinion broached in one or two of the letters following; not to add the tardy encouragement that resulted from some of those instruments that I had published, notwithstanding their efficacy had been proved and certified under the hand of our late experienced physician, Dr. Kerr. See the *Edinburgh Medical and Surgical Journal* for July 1820, for an example, detailing the construc-

tion of an instrument for reducing the dislocated shoulder, accompanied with an engraving.

[We have read the references alluded to in the course of this paper, and deem them perfectly satisfactory on the points to which they relate; but they are too long for insertion.—E. G.]

Trusting the perusal of the foregoing letters will satisfy your impartial readers, in respect to the lithontrip-tor originating with me, I shall close my paper with a few remarks on the apparatus, an account of which I published in 1819, and on the process of lithotritry in general.

Much stress is laid upon the advantage accruing from the discovery of the urethra admitting the introduction of straight sounds. Now, Sir, in this, as in some other statements, either an error or a wilful oversight occurs; for, if the apparatus I published be examined, it will be found perfectly straight, the curved part being confined to that portion which is to form the forceps; a shape which, unless I am essentially mistaken, even to a superficial mechanist must afford, when open, a far readier construction for grasping a stone, gravitating to the bottom of a concave cavity like the human bladder, than any diverging branches can do (however numerous) if projecting in a right line from the urethral canula.

Notwithstanding that some few years have elapsed since my attention was occupied in balancing the several advantages depending on diversified construction in the employment of the instrument, I well remember that the articulated extremity adopted in the construction of the forceps was preferred to the idea of grasping the stone by an approximation of pointed branches, which, instead of presenting one point, as in the articulated forceps, to the parietes of the bladder, would hazard three or four.

It is also demonstrable that the angular shaped opening assumed by the expansion adopted in the joint-pointed forceps, is well calculated, from the increased points of contact it affords in retaining the stone, to secure it against revolving, when its surface is under the action of the several spring rasps and drills specified in my publication.

That time and future discoveries in the improvement of the instrument, will establish lithotritry as a process su-

perseding lithotomy, I have never entertained a moment's doubt; and although unavoidable failures, and the accidents that will occur from the apparatus falling into the hands of individuals incompetent either to apply or appreciate its advantages, may, in the introductory æra of its employment, occasionally retard its success, future generations, from having timely recourse to its use, when the calculi are small, will practically learn to estimate the discovery.

I am, Sir,
Your obliged servant,
JOHN ELDERTON.

Northampton, Oct. 29, 1829.

CASE OF THE
CURE OF OPEN CANCER

By the Exhibition of the Chloride of Soda.

By THOMAS BUCHANAN, C.M.

To the Editor of the London Medical Gazette.

SIR,

I SHALL feel obliged by the insertion in your valuable Journal of the following history of a case of open cancer, cured by (what I presume to be) a new mode of treatment, after other modes had failed.

Jane Spencer, ætat. 53, of Burton-Pidsey, in Holderness, was under my care, about two years ago, for cancer of the right mamma. She had been several years affected with this dangerous and insidious disease, and had applied to various practitioners, in particular to the late Dr. Alderson, who advised extirpation as the only means of saving her life. When she applied to me the right breast was ulcerated to the extent of about two inches in diameter, including part of the nipple, and extending towards the axilla, with darting pains in the breast, thorax, and armpit. As the patient was determined against any operation, I applied the tincture of iodine over the whole of the breast, and dressed the wound with the ung. resin. comp. The ulcer healed gradually, but slowly; the pains diminished speedily; and in four days from the first application she was entirely freed from suffering. The parts, when healed, remained considerably indurated, but shewed no loss

of substance. This woman was one of those patients mentioned in my late work*.

In this state the breast continued nearly twelve months, when, in the beginning of June 1829, the whole of the indurated parts were thrown off, leaving a foul fetid ulcer of upwards of two inches and a half in diameter, which speedily discharged a quantity of thin, bloody, fetid sanies. All her former symptoms of darting pains in the breast, thorax, axilla, and abdomen, returned with redoubled violence.

The patient continued to have the ulcer dressed with such ointments as she could procure, until it became so nauseous, from the fetid smell of the discharge, as to affect, not only her own health, but that of her son, who dressed the wound. In this state she came to Hull, and applied to me, alleging, "that as she had found benefit formerly, she felt assured that I could do her good this time also." Having, prior to this period, frequently used a weak solution of the chloride of soda as a gargle in ulcerations of the mouth and throat, as well as in foul ulcers, I was induced, from these circumstances, to apply this powerful medicine in the case before me, and of the following strength:

R Liq. Chlor. Sodæ ʒvi.
Aqæ Distill. ʒviiij. M. ft. Lotio.

I dipped a pledget of lint into this lotion, and applied it to the diseased portion of the breast, with directions to keep the parts constantly moist with it; and also take two table-spoonsful of the solution three times a day.

The following day the discharge was changed to the colour and consistence of cream, totally divested of its fetid disagreeable smell. The ulcer healed rapidly; the whole of it was soon covered with healthy skin; forming, however, a considerable depression, occasioned by the loss of substance, as if part of the mamma had been dug out. The cure was completed by the latter part of June, 1829, being little more than ten or twelve days from the time of the first application of the solution of the chloride, and with only six bottles of the above, which were used indiscriminately as mixture and lotion. The patient was employed in the harvest

* Essay on the Treatment of Diseased Joints, and the Non-union of Fracture, &c.—Longman, Rees, and Co. 1828.

following, and as she expressed it, "wrought in better health and spirits than she had done for these last twenty years."

It may perhaps be asked, that as I lay claim to originality in the mode of treatment, why was this case not published prior to that of Mr. Fielding, of this place? To this I beg leave to reply, that I wished to ascertain whether or not the cure would be permanent; and also to collate a few similar cases before publication, and thereby, if possible, obviate any unfavourable impressions which your late critique on my work might create, where it was remarked—"Mr. Buchanan undoubtedly merits commendation for the zeal he has displayed in his trials of the medicine (iodine), however divided opinion may be on the results. For our parts, we believe the author has been led away by that leaning in its favour which all men must feel in pursuing a particular inquiry*."

Bearing in mind these circumstances, I therefore abstained from publication on this subject, and waited patiently the result of time, that great test of human discovery, in order to remove any shadow of doubt as to the permanency of the cure. But learning, through the medium of the Gazette (No. 92, p. 430) the very excellent cure of an open cancer made by Mr. Fielding, I then certainly thought it my duty to lay before you the history of the case.

Enclosed is a note received from my friend, Dr. Chalmers, one of the Physicians to the Hull Infirmary, after his examination of the patient, expressing his opinion of the cure. Your insertion of the history of this case in your valuable Journal, will much oblige, Sir,

Your constant reader,

THO. BUCHANAN.

Hull, Oct. 22, 1829.

FISSURED NIPPLES.

To the Editor of the London Medical Gazette.

Sloane-Street, Nov. 2, 1829.

SIR,

HAVING succeeded, à merveille, in curing fissured nipples, long an oppro-

brium of our art, by means of the Argenti nitras in substance, I cannot in my conscience refrain from making it known, through the medium of your pages, for the benefit of the sex, and the credit of Mr. Higginbottom.

I am, Sir,

Your obedient servant,

E. BOWDEN, Surgeon.

TIC DOULOUREUX.

To the Editor of the London Medical Gazette.

SIR,

HAVING lately met with a case of tic douloureux, which was effectually relieved by the use of carbonate of iron, I have ventured to transmit it to you for insertion, should you think it worthy a place in your valuable Journal.

A lady, aged 22 years, of sanguine temperament, had been subject to occasional attacks of tic douloureux, affecting the nerves of both cheeks; the paroxysms generally happening upon each recurrence of catarrh, to which she was very subject. During the first or second attacks of the former, the periods of exacerbation were but short, and the application of anodyne fomentations afforded decided relief; but within the last few weeks the disease had occurred more violently, and with shorter intervals. The excessive violence of the pain prevented her from enjoying sleep, except during an occasional hour when there was some remission of the pain. She had never experienced tooth-ache, and the teeth appeared perfectly sound. The anxiety, combined with the almost perpetual agony which she endured, reduced her from a state of robust health to that of nervous debility, attended with anorexia, &c. She had employed, by the suggestion of her medical attendant, stimulant and anodyne liniments and fomentations; aperients and quinine internally, &c.; and those domestic external remedies which had previously afforded signal relief, but now without producing any permanent, and scarcely even temporary relief; when, at my request, she was induced to try the effects of the carbonate of iron. She began with one scruple, four times a-day, in treacle, with directions to add five grains daily, till she took two scruples

* Medico-Chirurgical Journal, Dec. 1828.

for a dose. This, from the size of the powder, or from its being unpleasant to her, produced slight nausea, but was persisted in for a week, at which time the pain was very considerably abated. At the expiration of the second week the nausea ceased; the pain had entirely left her; her appetite returned, and I directed her to adhere to a milk diet. At the termination of the month from the first dose, she had recovered her strength greatly, and had regained the ruddy colour of the cheeks, which for a few months had left her. She continued the use of the carbonate of iron, but decreasing gradually the quantity till she took four grains for a dose; she then desisted altogether, and has not had a relapse since. By inserting this you will oblige,

Your constant reader,
T. R. COOPER.

Guy's Hospital, Nov. 2d, 1829.

ASSURANCE COMPANIES.

To the Editor of the London Medical Gazette.

SIR,

It is not at all an unusual thing to hear medical practitioners speak with much asperity of the various Life Assurance Societies, and always upon two grounds of complaint:—first, on account of the unhandsome manner in which it is alleged these societies sometimes request, or require, information respecting the health of persons desirous of being assured; secondly, because the letter of application is not accompanied with a fee, which, it is contended, ought always to be given for a professional opinion.

It is far from my intention to offer a defence of those who omit to make their applications for the necessary information in the most polite and courteous manner. The wording of their letters may, perhaps, in many instances, be calculated to stir up angry feelings in a sensitive mind; and if so, it would be prudent in the offices to amend any expressions that may be likely to give offence. One office, indeed, (I hope but one,) is guilty, on these occasions, of a greater insult than men of probity and honour can easily bear; for it scruples not to hold out a threat to those whose statement is

wanted, that *the answer will be filed**: thereby insinuating that the physician, or surgeon, to whom they apply, would, if not deterred by the threat of having his letter filed, be base enough to certify falsely respecting his patient's health.

If to such an application as this an answer be at all deigned, it ought, I grant, to be paid for by a fee, for no board of directors has a right to threaten with their vengeance those to whom they apply, unless they have given the *quid pro quo*—an adequate gratuity.

But under the ordinary circumstances of an application of this kind, ought a fee to be expected?

It is a *sine qua non* with all the assurance companies, that the person seeking to be assured shall refer to some respectable householders to speak of his moral character, his mode of living, and the general state of his health. As a preliminary step, he is required to sign a proposal-paper, setting forth his name, age, abode, occupation, state of health, &c.; and in this proposal-paper he is further required to insert the names of two or more persons of good reputation (one a medical man), who can give an attestation to the effect above-mentioned; and till such proposal papers are duly signed, and till such testimonials are before the directors, no application can be attended to, or policy be granted. This is a vital regulation in all Life Assurance Societies, from which there is no deviation.

References of this kind are, of course, made only to friends, and it is naturally supposed that the gentleman who is the regular medical attendant upon the person to be assured, or his family, is sufficiently a friend to furnish the necessary testimonial without a fee. With just as much reason as the medical man claims a fee for his testimony, might the other persons referred to claim a remuneration for theirs: but such a claim was never heard of; nor could the business of Life Assurance be easily carried on, if such a claim were enforced.

The question is often asked, "would any lawyer reply to such a letter without being paid for it?" Yes: lawyers sign such testimonials without a fee; the clergy do it without a fee; soldiers, sailors, magistrates, country gentlemen, bankers, merchants, tradesmen, clerks in public offices, all classes of society, agree in forwarding this necessary

* This is done by the Rock.—E. G.

document, without putting their friend who requests it to any expense. Some of the medical profession, probably from not having duly considered the subject, for they are rarely behind the rest of the world in liberality, are offended if they are not paid for this piece of civility.

Suppose the fee given; from whom is it to come?—from the party to be assured? What! will a medical man of reputation take a fee for certifying that the patient, whom he has known for years, is in good health?—or, suppose his health not to be good, will he take a guinea from his patient, and immediately report to the assurance office that his life is hazardous? Can he put the fee into his pocket with one hand, and with the other sign an unfavourable report?

But it may be replied, the office ought to give the fee*. Will this mend the matter? Will it not rather tend to create a jealousy on the part of the patient against his medical attendant? Particularly if he should be rejected by the office, is he not likely to conceive that the fee has tended to produce a more unfavourable report than would otherwise have been given?—that the doctor has, in fact, been bribed to set a mark upon his patient?

On the whole, I cannot do otherwise than believe it desirable that no fee should pass upon these occasions, and that the medical attendant upon a family will be satisfied that he can more conscientiously give an opinion, if, from neither party, he derives any pecuniary emolument.

F. R.†

October 28, 1829.

* It would not be possible for any assurance office to exist long if this were to be generally done; and if not generally, how is it to be done at all? Every assurance office has numerous applications made to it, on the behalf of parties who either do not mean to effect assurances at all or alter their minds afterwards; or wander from office to office, to discover at which they can get the assurance effected upon the most favourable terms. Taking all the offices conjointly, these non-effective applications must amount to some hundreds every year. If the offices were to fee the medical attendants upon families, for the information they seek after, it must be conditionally—that the assurance is effected; and the physician, or surgeon, would have to be looking out, week after week, to ascertain whether his patient was assured or not. Paltry!

† There is no signature in the original, but we think it better to attach one, in case of the paper being referred to by any other correspondent—E. G.

SUUM CUIQUE.

To the Editor of the London Medical Gazette.

SIR,

It is too much the fashion among us, when complacently descanting on our correct views and improved modes of investigation, to allude to the older medical authors with a degree of contempt which I fear leads us to an undue neglect of their writings, and leaves us in ignorance of many valuable facts and observations which, if properly prosecuted, would conduce to the attainment of that perfection in our art which it is yet far from possessing. There is now such a crowd of labourers in the field that we forget the fathers who first broke the ground, and the successive cultivators, who deserve our gratitude for so many obstacles encountered and overcome.

A little more attention than is usually devoted to the labours of our predecessors would also, in no small degree, tend to diminish an evil loudly complained of—viz. the multitude of authors who, from an ignorance of what has been done before them, impose upon you the task of reading and reviewing the “results of observations” made and recorded before they were born; and not a few among us, whose characters ought to protect them from any suspicion of literary dishonesty, would escape the charge of plagiarism in which an acquaintance with past medical literature now and then involves them.

But, from the disrepute into which our ancestors have fallen, and the necessity supposed to exist of keeping up our stock of knowledge by every man bringing his contribution monthly and annually into the market, our very contemporaries are likely to be numbered with the forgotten dead, and a work which is ten years old becomes obsolete as a matter of course. An amusing illustration of such a consequence is given by yourself in a late number, where Dr. Gooch is rated soundly by a critic for pilfering from a neighbour what, on a little investigation, turned out to have been, for many years, his own *bonâ fide* property. In your last number, likewise, two instances occur in which originality is assumed, where, but

for want of acquaintance with what was done before, candour, I am sure, would have prevented any such assumption. Mr. Lawrence, in detailing the distinguishing characters of inflammation, observes, that the view exhibited from the appearances it presents in an external part, has been generalised, and made a kind of representation of what occurs in inflammation in the body at large. "Hence," he continues, "inflammation of all parts has been said to consist in the combination of the four circumstances I have already detailed, viz. redness, swelling, heat, and pain: But I think, in order to make the enumeration of its characters complete, there should be two other characters added to these: we should take into view that important result—the interstitial deposition into the substance of the part, and we should also include in our view an event which is equally important—the impaired or suspended function of the organ affected." Now to learn whether or not it was left for Mr. L. to complete, by this addition, the characteristics of inflammation, let us turn to old Cullen's definition of phlegmasia. "*Febris synocha; phlogosis (partis externæ, rubor, calor, et tensio dolens); vel dolor topicus, simul, læsa partis internæ functione;*) sanguis missus et jam concretus superficiem corraceo albam ostendens." In this short definition, then, the best perhaps in nosology, the characters necessary, according to Mr. Lawrence, to constitute inflammation, were comprehended half a century ago.

Mr. Jewell, in directing attention to what appears a very rational piece of practice, favours us with his opinion of the most frequent cause of vaginal discharges, as being *the result of a strict investigation* into the numerous causes of leucoidal complaints which have fallen under his observation. This cause is no other than the sub-acute or chronic inflammation of the cervix uteri, about which so much has been written, with the view of instituting a rational practice in female discharges, by those ancient worthies, Mr. John Burns and Dr. Charles Clarke.

I have the honour to be, sir,
Your humble servitor,
JONATHAN OLDBUCK.

Monkbarns, Nov. 1, A. D. 1829.

ANALYSES & NOTICES OF BOOKS.

"L'Auteur se tne à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Principles of Military Surgery; comprising Observations on the Arrangement, Police, and Practice of Hospitals; and on the History, Treatment, and Anomalies of Variola and Syphilis. Illustrated with Cases and Dissections. By JOHN HENNEN, M.D. Inspector of Military Hospitals. Third Edition, with a Life of the Author. By his Son, Dr. JOHN HENNEN. 8vo. pp. 583.

WITHIN the last half century every science has made rapid progress; and, happily for humanity, none has improved in a more conspicuous manner than military surgery. It is not very long, as our author has remarked, since one of the most enthusiastic medical philosophers observed, that "practice, not precept, seemed to be the guide of all those who studied in this branch; and if we observe the practice hitherto pursued, we shall find it very confined, being hardly reduced to the common rules of surgery, and therefore it was hardly necessary for a man to be a surgeon to practise in the army."

A great change has taken place since the period here alluded to, and we are chiefly indebted for it to such works as the one before us; which carries proof with it, that though military surgery was then little better than a rude craft, it is now reduced to a science, based on ample experience and philosophic reasoning. At that time obscurity and neglect were the portion of its followers; honour and fame are now the rewards of well-directed talent; and to be convinced that they have not been held out in vain, we have only to recollect the names of some of our contemporaries; of Larrey and Percy; Hennen and Guthrie; and many others, whose valuable labours have so materially improved, not only military surgery, but the whole science.

Prefixed to this edition we have a life of the author, by his son, in which a very interesting sketch of his career is given.

"The lamented author of the 'Principles of Military Surgery' was born on the 21st of April, 1779, at

Castlebar, County Mayo, Ireland; and after a career of nearly thirty-one years, spent in active employment, and entirely devoted to the public service, died at Gibraltar, of the yellow fever, on the 3d of November, 1828, aged forty-nine years and six months."

He commenced his professional studies under his father, who was a medical practitioner, and attended the county infirmary. At the conclusion of his time he went to Edinburgh, and studied under Monro, Cullen, and Black. In March 1798 he received his diploma from the College of Edinburgh; and in 1800 he was appointed assistant-surgeon to the 40th foot. In 1809 he was ordered to Spain, where his zeal and attainments soon attracted the attention of the head of the medical department, Sir James M'Grigor, who has always shewn himself the patron of merit, and by whom he was subsequently placed in charge of some of the most important surgical hospitals in the Peninsula.

In the peace, in 1814, he retired to Scotland, for some time, on half-pay, and entered into private practice at Dumfries. During this short respite from active employment, he began to arrange the materials which he had collected whilst engaged in his arduous duties with the troops in the Peninsula, and planned his work on "Military Surgery."

In 1815 he was again called into active service; and after the battle of Waterloo he had the sole superintendence of the wounded general staff. He was afterwards removed to Edinburgh, where he published the first and second edition of this work, and for which he received from the Emperor of Russia a magnificent diamond ring, "as a mark of his high approbation of Dr. Hennen's work on Military Surgery."

In the beginning of 1826 he was placed in charge of the medical department of Gibraltar. In August 1828 a fever made its appearance, and soon assumed the character of former epidemics. Dr. Hennen's exertions were unremitting, night and day. On the 28th of October he was himself attacked. He still, however, continued in the performance of his duties, and up to a few hours of his death he continued to dictate letters, and sign the official papers, &c.

A subscription was immediately entered into by all classes in Gibraltar, as well as in London, Dublin, and Edinburgh, for the purpose of erecting a monument to his memory, on which an inscription has been engraved, testifying his high worth.

The alterations which this work has undergone for a third edition are not very important. The plates, which added to the expense of the second, have been omitted, we think, with advantage. There are a few additional observations, and many references to other works: it altogether bears the marks of a very careful revisal.

At the conclusion of the introductory remarks, Dr. Hennen observes—

"At the termination of a series of wars, which for a large portion of a century have desolated the fairest regions of the European world, and drenched their fields in blood, the medical philanthropist will naturally ask, what results have accrued from such ample sources of experience? what progress has been made in softening the miseries of pain and disease, and in extracting from such multitudes of victims, antidotes to the waste of human life? The younger practitioner, also, who may enter the service of his country, will inquire where am I to collect the fruit of that experience, with which so many campaigns have enriched my predecessors? and how, if the opportunities come within my reach, am I best to avail myself of them? It is in some degree to answer these interrogatories that I have ventured to make the following observations."

The value of Dr. Hennen's work is too well appreciated to need any praise of ours. He has here beautifully explained the object he had in view in writing it; and the high estimation in which it is held, proves how well he acquitted himself of his task. We were only required, then, to bring the third edition before the notice of our readers; and having done this, we shall merely add that the volume merits a place in every library, and that no military surgeon ought to be without it.

ANALYSES OF BRITISH MEDICAL JOURNALS.

EDINBURGH MEDICAL AND SURGICAL JOURNAL.

October 1829.

Quarterly Report of the Edinburgh Surgical Hospital from May to August 1829. By JAMES SYME, Esq. Fellow of the Royal College of Surgeons, and Lecturer on Surgery.

CIRCUMSTANCES, which it is unnecessary for us to enter upon, induced Mr. Syme, of Edinburgh, to institute a "surgical hospital" for twenty patients, and the present paper contains an account of the most interesting cases which occurred during the first three months of its existence—viz. from May to August 1829. Some of these will be given in our general collection of hospital reports. It may be proper here to mention that the case of excision of the upper jaw, detailed in the Gazette, vol. iv. page 215, did well, the patient being entirely relieved from his complaint, and having no inconvenience left except a small gap in the cheek.

Case of a Tumor of the Radial or Spiral Nerve of the right Arm, removed by HARRY LEEKE GIBBS, M.D. Member of the Royal College of Surgeons of London.

This case was first published in the Gazette, vol. iv. page 269, to which we refer.

Observations on the Ophthalmia Neonatorum, or purulent Ophthalmia of Infants. By J. H. WISHART, Esq. F.R.S.E. Surgeon to the King in Scotland.

After describing the phenomena usually presented by ophthalmia in young children, Mr. Wishart, in alluding to the causes, observes, that more than two-thirds of the infants affected with this disease are born of mothers labouring under a mild form of leucorrhœa; and although he remarks that it is difficult to determine whether the occurrences are necessarily or accidentally connected, it is obvious that he inclines to the former opinion. He adds, that the disease always has a certain duration,

never yielding in less than four weeks, and often extending to ten or twelve, but that it only assumes a great degree of intensity where the children are exposed to cold damp air, or are ill fed, and badly treated. Of such papers the practical points are of most value, and to these we now direct attention.

"The mode of cure which I have uniformly found successful, is the following:—

"If the patient comes under my care in one or two weeks from its commencement, I immediately wash away the puriform matter which glues down the eyelids, with a little warm water; and then, with a small conical-pointed ivory syringe, I inject the following eye-water:—

R Sulphatis Zinci scrupulum, Aquæ fontis uncias decem; Solve, et adde Liquoris subacetatis plumbi semidrachmam et Tincturæ Camphoræ drachmam vel drachmas duas. Misce et cola,—

At first diluted with a little warm water, to bring it to a proper temperature, as it always answers best at first to use it tepid, especially in very cold weather. This is repeated three times a day in ordinary cases, or every hour or two if the quantity of the discharge is very great, and is rapidly collected. In young infants the strength must be determined by the length of time they cry after the use of the collyrium. If the child continues to cry bitterly more than ten minutes, I consider it necessary to dilute the solution; but although they cry violently during the time of the application of the remedy, I have generally observed that they are more easily pacified the more frequently it is used. The degree of pain is also expressed by the contraction of the eyebrows and upper eyelid. The attendants are directed to prevent as much as possible the subsequent accumulation of the discharge, by washing it away as soon as it is observed with a little of the above-mentioned eye-water, and at night a little of the ointment of the oxide of zinc is insinuated between the eyelids; and in general, although they cry very much during the washing, the ointment does not seem to give them any pain. In some cases, I have seen considerable benefit from the application of a single leech to the outer angle of the eye, especially when we suspect that the inflammation is extending to the eyeball.

" In a few days the swelling and redness of the eyelids diminish, and then the ointment may be applied after using the eye-water. If, on attempting to open the eye, the lids seem very turgid, or if a little blood is forced out by the pressure, the lids should be freely scarified, and the bleeding encouraged by fomenting with warm milk and water. If at this time, as frequently happens, the upper eyelid is everted, the scarification is the more easily performed; but care should be taken to replace the eyelid as soon as it is done. This is readily effected by gently pressing the edge of the tarsus with the finger, when the child ceases crying.

" In the course of two weeks, if the cure goes on well, the swelling of the eyelid subsides, and the discharge acquires a watery appearance, as if mixed with the tears; the infant opens its eyes for a short time in the evening, and they are only glued down in the morning. At this period I usually change the collyrium to a weak solution of the muriate of mercury*, with the addition of the vinous tincture of opium; the red oxide of mercury ointment may be substituted for the zinc ointment; and it may be applied three times a-day, if the eyelids have still a tendency to adhere. At the end of a month it is generally unnecessary to continue the use of the syringe; but the eye should be carefully washed, by dropping a little of the collyrium into the hollow at the inner angle of the eye, and by gently separating the lids, it passes readily over the surface of the eye and lids.

" As it sometimes happens that the patient cannot be seen so often by the surgeon as the urgency of the case may require, and as the use of the syringe requires more skill and attention than the common attendants of children are capable of bestowing, I have found it necessary to direct the eye-water to be applied in the following manner:—A piece of soft sponge is to be dipped in the collyrium after it has been properly warmed; with this the edges of the tarsus are to be gently bathed, until all the hardened mucus is washed away, and the eyelashes separated from each other; the upper eyelid is then to be carefully raised, that the matter collected under it may be allowed to flow out. When the eyelid is thus elevated, the

soft sponge is to be squeezed at the inner angle of the eye, that the fluid may pass over the conjunctiva and eyeball. Besides this, considerable benefit will be derived from fomenting the eyelids two or three times a-day, and also during the night with the same collyrium*. The fomenting should be continued for nearly ten minutes each time; but the mother or nurse must be cautioned not to allow the cloths to become cold, and after fomenting the eyelids and surrounding parts, they should be carefully dried with a warm cloth; and during severe cold weather, compresses of two or three folds of soft linen should be applied over the eyebrows and cheeks, to guard them from the cold."

In preventing the accession of the disease, Mr. Wishart lays some stress on curing the leucorrhœa of the mother previously to her delivery, and afterwards suggests the administration to the parent of cubebs—that is, if she suckles the child. Of this last plan, all that the author says, is, that he is satisfied it is safe, but has not made up his mind as to its being actually beneficial.

—

Observations on the variety of Dropsy which depends on Diseased Kidney.
By ROBERT CHRISTISON, M.D. &c.

This paper is of considerable interest: it consists of some well detailed cases of dropsy, the general results of which fully confirm the views of Dr. Bright, as published in his valuable "Reports of medical cases." The dependence of dropsy on organic disease of the kidney is a very important pathological consideration, and that such is more frequently the case than we have hitherto suspected seems the necessary consequence of a statement, made by Dr. Christison, that there have been about twenty cases of this nature treated at the infirmary of Edinburgh during a twelve-month. It will be remembered that, according to Dr. Bright, (see Gazette, vol. i. pp. 88 and 122) the disease of the kidney, when fully developed, exhibits the appearance of a yellowish granular formation in its substance; and that this is always found after death where there has been albuminous urine during life, the urine containing but a small proportion of salts, and less urea than

* R. Mur. Hydrarg. gr. i. Aq. Rosæ ʒvi. solve et adde vin. opii ʒiiss. M. ft. collyrium.

* The application of warm poultices is always attended with the most deleterious consequences.

usual. The disease being indicated by pain across the loins or belly; by derangement of the stomach; and by purple urine, as if it were mixed with blood—or this actually being the case. This condition he farther states to be accompanied by a tendency to internal inflammation, and that bleeding is frequently the most efficacious remedy.

In the form of dropsy alluded to by Dr. Bright, in his reports, and Dr. Christison, in the paper before us, a diminution in the quantity of urea contained in the urine is a striking character; and this probably led to the idea that it might accumulate in the blood, as was found by MM. Prevost and Dumas to take place in dogs, when they extirpated the kidneys; an experiment, by the way, which carried with it the necessary inference that urea is not formed in the kidney, but merely eliminated by that organ from the blood, in which it had previously existed. One of the most important parts of Dr. Christison's cases relates to this point, for he proves more clearly than Dr. Bright had done the occasional existence of urea in the blood of patients labouring under this form of dropsy—as will appear from the following interesting case, which also illustrates the mode of conducting the analysis:—

“ Francis Magee, aged 57, a weaver, at the time of his admission into the infirmary on the 5th August, 1828, had been affected for three weeks with considerable œdema, and some swelling and firmness of the belly. He had also occasional vomiting in the morning, and dull pain on pressure in the pit of the stomach and along the margin of the ribs on the right side. He had likewise frequent cough, with difficult expectoration of tough opaque mucus, and considerable difficulty of breathing. The chest sounded every where loudly on percussion; and both acts of respiration, but particularly expiration, were prolonged, inspiration being also indistinct, expiration distinct, sonorous, and sibilant. The pulsation of the heart could not be felt with the hand when he lay on the left side; and with the stethoscope both sound and impulse were feeble. The pulse too was feeble, and only 52 in the minute. The tongue was furred and breath fetid; the bowels required the frequent use of laxatives; the urine was of natural quantity, but exceedingly pale, being of

the lightest possible straw colour, and depositing a moderate quantity of white flakes when heated.

His pectoral complaints were of eight years standing, and began subsequently to the healing of an old ulcer on the leg, which had been occasionally healed, though only for a few weeks at a time, during twelve years previous to its final cicatrization. About a year before his admission into the hospital his breathing got worse, so as to annoy him when at work. About that time he had also a comatose attack, which lasted a day, and was removed by blood-letting. After that his urine had been always pale but natural in quantity. For two months before he entered the hospital he had pain in the loins, difficulty in passing urine, and frequent attacks of vomiting.

“ He was ordered ten drops of tincture of digitalis thrice a-day in an ounce of infusion of cassia, and likewise a mercurial pill every evening. Laxatives were also given from time to time. On the third day of this treatment the urine was 104 ounces, and had a specific gravity of 1007.9. The œdema was lessened; and the action of the heart both to the hand and to the stethoscope was natural, though rather feeble. On the 11th August the œdema was gone, the ascites nearly so; but his breathing was as laborious as ever, and he complained of pain round the whole lower margin of the chest, particularly in the loins, where pressure made the pain shoot towards the stomach. The digitalis was discontinued, and a squill mixture ordered in its place.

“ From this time the urine began to decrease in quantity, till on the 16th it was only 40 ounces daily. Its specific gravity was 1008.4, it was as colourless as ever, coagulated more abundantly when heated, and contained very little urea. There was no return of the dropsical swellings, but his difficulty of breathing and cough were not in the least relieved. Next day the breathing was worse. He also became affected with headache, drowsiness, contracted pupil, some livor of the face and tremors of the hands. The pulse was 60 and full, and the tongue brown on the centre. Fourteen ounces of blood were therefore taken from the arm, with some relief to the dyspnoea; and the blood was very buffy in one cup. The squill was now abandoned and the digitalis

resumed. On the 18th the symptoms connected with the affection of the head were rather increased, and he was feeble and much exhausted. The urine was only fifteen ounces. A brisk laxative and a purgative enema were ordered, leeches were applied to the temples, and subsequently a blister to the head; but without any advantage. His stupor and tremors got gradually worse and worse; he complained of tenderness over the whole belly; the urine on the 19th was only twelve ounces; on the 20th twelve ounces were withdrawn by the catheter. On the morning of the 21st he died.

The whole urine passed during the last thirty-six hours of his life was two ounces. This had precisely the same external qualities as the urine previously passed, but had rather a higher specific gravity, namely 1009.5.

Inspection.—There was very little œdema of the limbs. The face was not livid, and the scalp was free of blood. The sinuses of the dura mater contained only a moderate quantity of blood; the arachnoid and pia mater, as well as the substance of the whole brain, were remarkably destitute of blood, and blanched. There was not above half a drachm of fluid in each lateral ventricle, and half an ounce in the base of the skull. Even in the base of the brain the vessels were unusually empty of blood. The cortical matter of the brain appeared less in thickness than natural. In the middle of the left *thalamus*, half an inch behind the anterior commissure, there was a cavity which would have held a cherry-stone; it was crossed by filaments of cellular tissue, walled in by a thin partition of condensed cerebral substance, but not surrounded by redness or softening.

“The pericardium and base of the left lung adhered to the pleura of the ribs by very old adhesions; and four ounces of clear serum were contained in the pleural sac of that side, but none in the pericardium. The posterior part of the lower lobe was very œdematous. The walls of the left ventricle of the heart were somewhat thickened, and its cavity contracted. The aorta was slightly and uniformly enlarged at the arch, and its whole inner membrane thickened, hard, and wrinkled,—the valves being also involved in this change of structure. On the surface of the right lung there were many old adhesions to the ribs; and in its substance a

great deal of œdematous infiltration. The fore part of both lungs was gray, strongly crepitant when handled, and slightly emphysematous,—the whole air-cells being somewhat enlarged. The nature of their structure in the posterior part could not be ascertained, on account of their state of infiltration. The greater bronchial tubes were filled with mucus. The blood was every where black and fluid.

“The stomach and intestines were healthy. The spleen was pale reddish-brown, firm, and composed of little radiated masses, (not unlike the mineral Wavellite in appearance.) The liver was somewhat larger than usual, but in structure perfectly healthy. The kidneys were both much diseased: the right was rather less than natural, externally rough with small irregular nodules and of a pale grayish-brown colour, internally of a pale grayish-yellow tint. The *tubuli uriniferi* were much nearer the surface than in the healthy kidney, greatly diminished in size, and pushed as it were outwardly by a deposit around the *pelvis* of grayish-yellow, indistinctly granular matter, into which also the whole cortical substance was converted, so as to have lost its usual fibrous appearance. Even the fibres of the *tubuli* were unusually pale, and the yellow matter was deposited among them. The *pelvis* of the kidney was small, the ureter pervious. The left kidney was very diminished in size, flattened and flabby. Its cortical substance was in the same state as that of the right kidney, but rather darker, and with a few distinct tubercles; and some grains were softened. The tubular portion was of a dark brownish-red colour, and not fibrous at all; and it contained several small watery cells, apparently the remains of the infundibula. The ureter was pervious. The capsular fat of both kidneys was indurated, and the tunica propria thickened and adhering.

“*Analysis of the Blood.*—About an ounce of blood was collected from the vena cava by an incision in the loins, great care being taken to keep it clean and pure. It was black, fluid, and nearly free of the odour of putrefaction. It was heated in a vapour-bath at a temperature a little under 212, and rapidly stirred as soon as it began to coagulate. A thick, brownish-red, granular mass being thus formed, a little distilled water was added; and after agitation,

the whole was filtered. A cherry-red fluid passed through, which at 212° deposited more brown flakes, and became wine-yellow in colour. This was evaporated nearly to dryness in the vapour-bath, at a temperature beneath 212° , during which a fetid odour was exhaled, exactly the same as that of the patient's breath during life. Just before the fluid began to acquire a syrupy consistence, a drop of it was treated with nitric acid, which rendered it opaque, and caused considerable coagulation; but crystals were not formed. The syrupy extract, when acted on by boiling alcohol, gave a pale wine-yellow solution, which was evaporated in a small glass vessel till it began to thicken. This extract had the same fœtor.

"On the addition of a few drops of nitric acid, the same odour was exhaled from it as from extract of urine, when similarly treated; and immediately fine, greyish-red, flaky crystals, of a pearly lustre, were formed in abundance, so as to thicken the whole mass. These were evidently scales of nitrate of urea."

Another inference of a consolatory nature, deducible from some of Dr. Christison's cases, would seem to be, that the organic change of the kidney may be arrested if discovered in its early stage—that is, some patients presenting the symptoms of it have been ascertained to have remained free from dropsy for several years after they had undergone proper treatment. The observations of both the able physicians alluded to agree essentially as to the power of various diuretics. Digitalis frequently acted well; but supertartrate of potass was, upon the whole, the most certain. Mercury has not, in the hands of Dr. Christison, produced, even when salivation resulted, those injurious consequences which Dr. Bright seems to apprehend.

Remarks on Amaurosis, with Cases.

By Dr. J. A. ROBERTSON, F.R.S.E.
Surgeon to the Eye Dispensary of Edinburgh, &c.

The term amaurosis, Dr. Robertson observes, is generally applied to all those cases in which vision is impaired or lost, in consequence of disease of the retina or optic nerve; it is usually accompanied with dilatation of the pupil, which remains immoveable; but the author of the present paper has more

than once seen it dilated and fixed, without vision being much affected. In one case this appeared to have arisen from an attack of iritis, during which the pupil was kept dilated by means of belladonna, and seemed to have contracted adhesions when in this state. Again, in some cases of amaurosis, the iris acts as in the healthy eye. Dr. Robertson thinks the disease more decidedly hereditary than cataract. The principal object of the paper, however, is to shew that pressure on the nerves of the eye, by the fulness of the blood-vessels in their immediate neighbourhood, is a very frequent cause of amaurosis, and, consequently, that depletion is often the most efficient remedy. For this purpose several cases are detailed, in which bleeding was of great service. These, however, were all recent cases, attended with symptoms of congestion, and in such only does the author profess to have found blood-letting decidedly beneficial.

While we admit the propriety of the remedy, we must observe, that the cases adduced appear to us rather to belong to those of apoplexy and its premonitory symptoms, than to what we usually understand by amaurosis. A continuation of the paper is promised.

On the Sounds produced by the Action of the Heart. By DAVID WILLIAMS, M.D., Physician to the North Dispensary, Liverpool.

Mr. Turner published a paper in the third volume of the Transac. Med. Chir. Society of Edinburgh, in which he argued against the explanation offered by M. Laennec of the sounds produced by the action of the heart. On applying the stethoscope we hear—first a dull and prolonged sound, and this is followed by a sharp quick sound; after which comes a momentary repose. The first of these sounds was attributed by the French pathologist to the contraction of the ventricles; the second to that of the auricles. This idea makes the contraction of the ventricles precede that of the auricles, an order the reverse of that which is generally admitted, and on this contradiction the objection of Mr. Turner chiefly hinges. Dr. Williams agrees with Mr. Turner in so far as regards the rejection of Laennec's explanation; but he does not think that the suggestion offered by

Mr. Turner admissible. All the practical deduction we have been able to draw from the paper is, that those who have paid most attention to mediate auscultation differ considerably in their opinions; and that some of the signs they have pointed out of disease of the heart are either fallacious, or require a sense of hearing of more than ordinary delicacy to detect them.

MEDICAL GAZETTE.

Saturday, Nov. 14, 1829.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."—CICERO.

LATIN EXAMINATIONS.

ONE of the barbarous customs which still survive in our great establishments for medical education, is that of examining candidates for degrees and licenses in the Latin language. It is curious that this abuse, handed down to us from the "good old times," has been so completely overlooked by contemporary writers. In this reforming age, one would suppose that so palpable a source of imperfection in our educational machinery could scarcely escape the censure which it deserves. With the inattention, however, but too frequently observable in our speculators on a great scale, the matter in question has been neglected as unimportant—perhaps as one that would fall betimes a victim to its own absurdity. It is to be hoped it may. But when we see the statutes and ordinances upon which the custom is founded adhered to with a pertinacity which promises it a lengthened existence, it is full time to call public attention to the subject. There is no knowing how much good may arise from the exposure of absurdity

and error, however trifling at first sight they may appear.

From the revival of literature in Europe, it is well known that for several centuries the Latin was the universal language—the great medium of instruction in every branch of human knowledge. Every treatise in law, physic, and divinity, was written, or at least published, in the Latin tongue; every Professor addressed his auditory in the same language. The first attempt ever made to shake off the pedantic yoke was by that extraordinary man Theophrastus Paracelsus, in his professorship at Basle, in the early part of the sixteenth century; but it proved a dangerous experiment. It was deemed as daring an innovation, or heresy rather, as that of his great cotemporary, who was at that very period reforming the language as well as the doctrines of the church; and to have presumed to break through the academic fashion by lecturing "in the vernacular," has ever since been recorded against Paracelsus as not the lightest of the high crimes and misdemeanors imputed to his charge. It is scarcely necessary to add, that his attempt did not succeed; the old system was resumed by his successors, and to this day the Latin is the prevailing language of the lecture-rooms throughout Germany.

The French very early manifested that decided partiality for their native tongue, for which they have ever been so remarkable; and they may boast of having been the first nation in Europe which asserted their own dignity, by abolishing the then degenerate Roman idiom as a medium of communication between the learned.

But in England, strange to say, notwithstanding the early reception which the Reformation obtained amongst us, the Latin language—"the language of Antichrist" (as some of the Scottish covenanters used to call it)—prevailed in

all our Universities until about the middle of the last century. It was about that period, or somewhat later, that the eminent political economist and moral philosopher, Adam Smith, broke the spell. The innovation escaped the censure of "the learned," and was gradually adopted in the schools; and at present, we believe, it would be as difficult to find a lecturer in any of our seats of learning speaking Latin *ex cathedra*, as it was formerly to hear one of those individuals condescending to speak in his mother tongue. Addresses in Latin are fortunately no longer heard in our Colleges, except, perhaps, an occasional sermon for a degree, or an oration in honour of a founder or a festival. How much were it to be wished that this reform had gone a step farther! but here it stopped, leaving the absurd custom of which we complain unreformed.

At a time when the Latin, as a spoken language, has become perfectly obsolete, and when science has become intricate and extensive, we find the Universities still adhering to the old leaven—still pretending to ascertain the merit of candidates for honours (at least for medical honours) through the medium of Latin examinations. And our learned Colleges of Physicians, too, follow their example.

Now, when the object is to ascertain the extent of knowledge acquired by the candidate, it would seem natural that the most familiar mode of expression should be allowed him by his judges, and adopted by themselves; and surely no one will venture to assert that a foreign, nay more, a dead language, can be spoken with the same freedom and fluency as one's native tongue. Why, then, persevere in its employment? Is it for ostentation sake—to impress the minds of the vulgar with reverence and awe? This is

pedantry, and mere delusion. It is quite too late a period in the history of human opinion to hope to gain respect by involving our proceedings in the petty obscurities of unwonted phraseology—it is an attempt at imposition unworthy of its supporters; but perhaps there may be some argument in favour of it, derived from the necessity of the case, or from expediency.

If we conjecture aright, the original intention of the institutors of Latin examinations was not so much directed to the dignity or respectability, as to the expediency of the measure. In their time the Latin, as we have already mentioned, was the medium of intercourse between the learned—the language of lectures and of books. The terms of art, the description of the parts treated of in anatomy, the crude notions of the day in physiology, and the science of disease, were all couched in the same idiom. The mother-tongue was defective in the necessary means of expression, and it was ordained, as a matter of course, that the proficiency of candidates who aspired to the honours of the profession should be ascertained through the ordinary language of literature and science. How completely the whole state of things is changed in our own times, it would be impertinent and commonplace in us to explain; but it is abundantly evident that no reason grounded on necessity can any longer be put forward as a pretext for the continuance of the practice. Nor is it less evident, that it affords no test whatever of the candidate's talents, or of the depth of his research in the acquisition of medical knowledge. Whatever profit in after-life he may derive from them (and we are fully persuaded of the solid worth of much of our neglected medical literature), the *student* is neither expected to be conversant with the works of Morgagni,

Baglivi, or Boerhaave,—not to mention others more antiquated; nor in the extensive range of subjects laid down for his examinations, would it be possible to form even a superficial acquaintance with those writers. Were there a course of reading of the latter description prescribed (as many of the authors to whom we have just alluded have never been translated into our language), there might be some shadow of reason for keeping up our familiarity with the corrupt Latin idiom of the schools; but, as it is, when new systems altogether prevail—when the older writers are treated with a contemptuous neglect—and when, above all, we can boast of a vernacular tongue, at once the most rich, copious, and expressive perhaps in the world—is it not the height of folly and absurdity to cramp ourselves with the fetters of a foreign and dead language*?

Another view of the case imperatively demands our notice. We feel it to be our bounden duty, as public journalists, to watch minutely over the interests of our profession, and to denounce, with severest stricture, any proceeding which may lead to the intrusion of unworthy members into it. We, therefore, cannot help farther considering the Latin system as eminently calculated to cloak the insufficiency of certain candidates, whilst it forwards the impudent pretensions of others. It is easy to conceive—nay, it is well understood by most of our readers—how, in examinations of this sort, the faltering and imperfect expression of a candidate, proceeding generally as much from ignorance of his business as from the difficulty of using a language which he is obliged to speak, perhaps, for the first and

only time in his life, is but too frequently imputed to the latter cause; while, on the other hand, an assumed boldness and flippancy will most assuredly carry a more confident, though, mayhap, an equally ill-prepared candidate, over a multitude of errors and mistakes: and all this, even supposing the examiners themselves to be the best prepared in the world for judging of merit through the medium of an “unknown tongue.”

Let us not be misunderstood: we should be sorry to be thought capable of decrying the usefulness of classical literature. As a branch of general knowledge, and as the best basis for the superstructure of a complete medical education, we hold it to be perfectly indispensable to the accomplished practitioner, both as a gentleman and a scholar. A familiarity with the classic writers of Greece and Rome will impart to his mind an elegance and elevation of sentiment — will improve his reasoning powers, and bestow on him a command of language scarcely attainable from any other source; and we cannot but express our regret that its great importance is so much overlooked in the multitudinous schemes for the improvement of medical education which hourly issue from the press. But surely classical literature has nothing to do with the barbarous system of Latin examinations. It is worse than barbarous; it has not a single good quality in its character to redeem it. That it is no test of merit, either in the candidate or his examiner, we have shewn; that it is injurious, and dangerous, inasmuch as it affords to unqualified persons an easy ingress into our profession, we have endeavoured to prove. We shall now merely add a few words on another of its characteristics, and have done with it for the present.

It is pretty generally known to what a low state the faculty in France was reduced by the exquisite ridicule of Mo-

* See Dugald Stewart's *First Diss. Sup. Encyclo. Brit.* for an interesting account of the present state of our native tongue. The late Marquis of Hastings, in an address to the members of the College of Calcutta, in 1814, paid a proud tribute to the strength and beauty of the English language.

liere; in fact the effects of his satire are felt in that country up to the present day. That there is no engine more powerful than ridicule, when wielded by an able hand, and directed against a system of no very sound constitution, is as familiar to our minds as a proverb can make it. And it should not be forgotten that it was on the mummery of Latin examinations that Moliere fastened the tenacula of his wicked wit. The concluding ballet of the "*Malade Imaginaire*" is indeed a legacy bequeathed to posterity with his dying breath*. Yet in these kingdoms the obnoxious proceeding has survived with extraordinary pertinacity of existence. The faculty has patiently endured the shafts of ridicule levelled at her by some of our ablest writers; but how much longer she will be able to withstand the attack remains to be seen. Even the lowest classes of society are every day growing more and more enlightened, and they are no longer to be imposed on by the plausible externals of ancient usages. In short, we have scarcely room to doubt but that the absurd ceremonial in question will ere long share the fate of many of its predecessors; it must shortly be reckoned among the vanities that are not. By the better sense of our contemporaries this relic of the wisdom of our ancestors will be abolished. For our own parts, we are almost ashamed of having attempted, in so serious a mood, to expose it. On reflection it looks somewhat like "breaking a butterfly;" yet the humblest exertion in the cause of truth and plain-dealing, possesses a degree of merit sufficient to save it from being contemned. We may even be tempted to add some further observations upon it on another occasion.

* Moliere died in enacting the character of Argan, in that admirable comedy.

MR. LAWRENCE'S LECTURES.

In our number of October the 17th, we stated that the insinuations in the *Lancet*, that Mr. Lawrence corrected the proofs of his lectures for that Journal, were wholly and unequivocally false. This has been confirmed by Mr. Lawrence withdrawing from the *Lancet* his permission to publish his lectures, and therefore it is unnecessary to dwell longer upon it.

But we also at the same time used these words—"It will scarcely be credited, but it is nevertheless literally true, that Wakley had the impudence to advertise the publication of that gentleman's (Mr. L.'s) lectures before he thought proper even to acquaint him with his intentions." The exact extent to which we were justified in making this assertion will appear from the following extract of a letter from Mr. Lawrence, dated Nov. 10:—"I do not know whether the observations in the latter (i. e. the passage from the *Gazette* quoted above) refer to the advertisement of my lectures in the *Lancet* without my consent to the publication, or to the advertisement. I am not aware that the Editor of the *Lancet* advertised these lectures before asking my consent to the publication. I gave no consent to the advertisement, nor was I aware, until you informed me, that they had been advertised." Although our accusation against the Editor of the *Lancet* was only verbally with respect to the advertisement of the lectures, and is therefore borne out by the above extract, still we must state, that the impression conveyed to our minds by Mr. Lawrence's language at the time the conversation took place was, that his expression of ignorance extended to the Editor of the *Lancet*'s intentions as to the publication of his lectures, and not as to their mere advertisement—which appears, from the above extract, to have been the case.

DR. BURROWES.

WE had intended to make some remarks on the extraordinary transaction in which this gentleman's name has lately been involved; but as in the following explanatory remarks he implies that more information will appear in a court of justice, we suspend our judgment till the whole evidence comes before us. Meantime we think it right towards Dr. Burrowes to give insertion to his explanation, so far as it goes.

From the Morning Chronicle:—

"I have called here (Police-Office) to-day to ask the courtesy of the Magistrates to allow me to make a few observations on the publication of the proceedings in the case of Mr. Anderdon, which took place at this office a few days ago. The impression on the minds of many persons after reading that report is, that I did not make any reply to Mr. Chambers, whose politeness I am ready to acknowledge, when I told him that I should go to consult the gentleman by whom I had been employed, and return as speedily as possible to this office with the result of the interview between us. I did go as I promised over to the house of one of the gentlemen in Lombard-Street, and saw him; but as it was deemed a matter of much consultation, we at once proceeded to the residence of his legal adviser. We were there obliged to wait some time, in consequence of the solicitor being engaged, before we could have the desired opportunity of an interview. As the case was one of considerable importance, and required much deliberation how it was to be proceeded in, we remained until the matter had been fully deliberated. I then wrote a note to Mr. Chambers, and sent it off immediately: it was three o'clock when the note left the solicitor's office, and I was not at all aware that the police office shut up at that-hour; neither was I conscious, until a day or two afterwards, that the communication had not been received during the hours of business. I hope, therefore, that I shall be exonerated from the charge of neglect in this instance. With respect to the report of the other circumstances connected with this peculiarly unpleasant affair, and

which appeared in the newspapers, I cannot say at present whether there are errors in it or not; because, if I entered into the merits of the question at present, I should be betraying a professional confidence reposed in me, which would be most improper on my part. Those who know me (said the Doctor) I hope will believe that I would not act in a case of such an important nature without the greatest deliberation. I have had two interviews with the Messrs. Anderdon, that occupied several hours; and finding that a medical examination, from the peculiarity of the case, could not be entered into at the time with any degree of propriety, it was therefore deferred. I trust, however, that in the course of the judicial proceedings now pending, facts will be elicited relative to this distressing business which will exonerate me from all blame as to the manner in which I have acted throughout. The reporters, I hope and expect, will do me the justice to make the present statement known, through the same medium that their former accounts obtained publicity; and I also entreat the public to suspend their judgments of my conduct in the affair until the issue of the proceedings which I have before alluded to are known."

PROCEEDINGS OF SOCIETIES.

WESTMINSTER MEDICAL SOCIETY.

Nov. 7th.

Divisions of Small-Pox.

DR. GREGORY stated, that, relying on what he read and had been taught in lectures, he had entered into practice with the impression that the severity of small-pox was, in the great majority of cases, in the direct ratio of the number of pustules; but that he had soon found other circumstances of more importance than the one alluded to, and had ultimately been led to arrange the different varieties of small-pox under the five following heads.

1. What he called the *superficial* form of the disease—in which the eruption, whether copious or scanty, was fully developed on the skin with a well-marked scarlet areola round the poek, and with little or no affection of the mucous membrane of the fauces or air passages. This form always does well,

however copious the crop of pustules may be.

2. The *cellular* form, in which the variolous action extends from the skin into the subjacent cellular texture, and in which the glands about the throat, axilla, and groin, become implicated. This extension of the disease is apt to shew itself at a late period, giving rise to boils, abscesses, and other mischiefs, which greatly retard convalescence, and occasionally prove fatal. He had known a patient die from an abscess forming under each scapula.

3. The *laryngeal* form, in which the variolous action extends to the mucous membrane of the fauces, larynx, and trachea, interfering essentially with the function of respiration, impeding the oxygenation of the blood, and being, in consequence, attended with a peculiar claret colour of the pustules. The other mucous membranes—as those of the alimentary canal, bladder, vagina, urethra, &c. are incapable of taking on the variolous action; but in the larynx it sometimes runs so high as to produce sloughing—a specimen of which the Doctor exhibited. Even the eye, which so frequently suffers from small-pox, Dr. Gregory affirms to do so from common inflammation only; the pustule on the cornea not appearing till the eruption is on the decline, and therefore not being a primary or essential feature of the disease. This form of small-pox is very fatal; the eighth and ninth days being those of danger.

4. Some persons, especially those liable to cerebral affections, die at an earlier period—generally *within* the first eight days. These cases are ushered in by fierce delirium, succeeded by symptoms of effusion into the brain. Corresponding appearances present themselves on examination after death. To this variety the Doctor gives the name of *nervous* small-pox; and he believes it to depend, not on inflammation, but on a specific or *variolous* action. That it is not, strictly speaking, inflammation, is rendered probable by the fact of the blood, when drawn at this time, not exhibiting the buffy coat, and by the little benefit derived from blood-letting.

5. The last variety is regarded as depending on the *dissolution* of the blood—marked by petechiæ, passive hæmorrhages, &c. From this Dr. Gregory never saw any patient recover who was not guarded by previous vaccination.

Rather an animated debate followed, the general result of which was, that most of those who had seen any thing of small-pox recognized the divisions proposed by Dr. Gregory as correct, and leading to useful practical consequences: still they were not admitted as distinct *species*, nor as having their seat in essentially distinct tissues—or, at least, when any besides the skin and mucous membranes were affected at all, such affections were held to be only common inflammation.

HOSPITAL REPORTS.

ST. BARTHOLOMEW'S HOSPITAL:

Case of extensive Inflammation and Suppuration of the Thigh, following Wound of Knee-Joint.

HENRY PHILLIPS, æt. 40, admitted into Pitcairne's Ward, under Mr. Earle, Sept. 13th. This patient, six weeks previous to his admission into St. Bartholomew's Hospital, had inflicted a wound on the inner and front part of the knee (which penetrated into the joint, dividing the integuments to the extent of two inches), while engaged in shaping the spokes of a wheel with a drawing knife. He was immediately conveyed to another institution. Extensive inflammation of the knee and thigh followed the receipt of the injury, which was not checked by the application of leeches and cold lotions, and in about a fortnight matter had formed in the upper and inner part of the thigh, for the discharge of which a small inefficient opening was made with a lancet. A thinnish pus continued to drain both from the artificial opening and from the original wound in the knee-joint, reducing the patient considerably; the integuments of the thigh acquired a very firm resisting texture, which went on gradually increasing; the accompanying debility became daily more manifest, alarming the patient for his safety; and at the end of six weeks he grew dissatisfied with his treatment, and, worn out with continued pain and mental anxiety, he was conveyed home, and placed himself under the care of a private practitioner. The gentleman who visited him, not feeling quite satisfied as to the nature of the case, and wishing for further advice, Mr. Earle was called in. The state of the patient at this time was as follows: Reduced almost to the last extremity, with a pulse small, thready, and scarcely to be felt; the whole body bathed in a cold clammy sweat. Mr. E. believed him to be in articulo mortis. The integuments of the thigh presented a perfectly firm, horny, or cartilaginous feel, not in the slightest degree yielding to the

pressure of the finger. There was at this time little discharge from either wound. Mr. Earle felt assured of the presence of deeply-seated matter, and of the necessity for its immediate evacuation. Nothing like fluctuation could be discovered through the hardened integuments. Mr. E. had not been apprised of the nature of the case, and was provided at the time with no other instrument than a common bleeding lancet: with this, however, an incision was made about six inches long, extending up the thigh. The lancet was first thrust directly downwards, till the shoulder was buried, and not till then did it reach the depôt of matter. The instrument was then carried upwards, cutting its way out with considerable difficulty, owing to the firm resistance offered by the horny texture of the parts. Another cut was made to communicate with a former opening. Matter followed in the whole track of the incision, and in this way a large quantity of sloughy portions and of sanious foetid fluid were evacuated. He was directed to take Carb. ammon. gr. v. 3tis horis, and lint was introduced into the wound. The patient felt relieved soon after; the pulse became more distinct; his feelings of alarm and nervous sensations gradually left him, and he felt more composed than he had done for some time previously. Mr. Earle had him removed to St. Bartholomew's Hospital, September 12th, where he continued gradually to improve. The hardened state of the skin and cellular tissue slowly disappeared, and with the use of quinine his strength was restored sufficiently to enable him to leave the hospital October 8th, with very good motion in the knee-joint, and feeling very grateful for what had been done for him.

Case of large Scrotal Hernia, reduced by general means.

John Ross, æt. 28, admitted Sept. 17th, into Powell's Ward, under Mr. Earle, with a large scrotal hernia of the right side. The man states, that, two years since, he ruptured himself while lifting a heavy weight. He felt something to give way at the time, and observed a swelling in the groin, which gradually increased, and descended into the scrotum. For the space of about two years he suffered no inconvenience from the rupture, which was always protruded during the day, and returned again upon his going to rest at night. During this time he never wore a truss. About three weeks before his admission, he found that he was unable to return the hernia as usual. He states, that, from this time, the swelling gradually increased in size, the scrotum being much more distended than he had ever observed it to be before; and its friction against the thighs causing him much uneasiness and pain, he was induced to seek relief

at this hospital. When admitted, the scrotum was found to be considerably distended with a hard and inelastic mass, which was supposed to consist of omentum; the testicle could be distinguished at the most inferior part of the scrotum; bowels not constipated. The protruded parts firmly resisted any attempts at reduction by the taxis; and as there were no urgent symptoms, it was resolved to give the emaciating plan a fair trial, with the view of lessening the bulk of the tumor by reducing the quantity of fat of which it was thought chiefly to consist. As Mr. Earle expressed it, he would try to convert his fat into soap, by the internal exhibition of the liquor potassæ.

The patient was put upon low diet, and the recumbent posture was strictly enjoined. He was ordered to take liq. potass. Mxx ter die; and with the view of assisting the absorbents, the unguent. hyd. was directed to be rubbed in so as to produce slight pyalism. The good effects of the treatment were in a short time manifest, and at the end of five weeks the plan had succeeded perfectly. The hardened omentum gradually softened and decreased in bulk, until it was entirely reduced. The neck of the sac was felt to be considerably thickened. October 24th he was ordered to have a truss, and discharged on the 27th.

Luxation of the Thigh Bone upwards and forwards on the Pubes.

Mary Hinds, æt. 63, was admitted into this hospital October 19th. She said that she slipped down stairs and fell on the right hip, with the leg under her. The dresser was not able to ascertain exactly the nature of the accident, but recognized the head of the bone, which obeyed the motions of the limb, in the groin. Mr. Vincent saw her on the 20th, and shewed the case to Messrs. Lawrence and Earle, when it was decided to be a dislocation upwards.

On examining the limb, it appeared about two-thirds of an inch shorter than the other; the toes everted and pointed downwards, so as not to allow the heel to reach the ground; the knee was also everted; the heel and knee could be brought close to the opposite limb; the femur was not bent either backwards or forwards with regard to the pelvis, and could easily be flexed to a right angle with the pelvis; it could not be rotated inwards, and but slightly outwards; by using a slight extension, the limb could nearly be brought down to its original length; the hip was flattened externally. Situation of the head of the femur, upon and rather to the pubic side of the inferior, anterior, spinous process of the ilium, having no muscle between it and that process; in front, and covering that part of the head nearest the neck, was the origin of the rectus muscle that arises from the inferior spine; external-

however copious the crop of pustules may be.

2. The *cellular* form, in which the variolous action extends from the skin into the subjacent cellular texture, and in which the glands about the throat, axilla, and groin, become implicated. This extension of the disease is apt to shew itself at a late period, giving rise to boils, abscesses, and other mischiefs, which greatly retard convalescence, and occasionally prove fatal. He had known a patient die from an abscess forming under each scapula.

3. The *laryngeal* form, in which the variolous action extends to the mucous membrane of the fauces, larynx, and trachea, interfering essentially with the function of respiration, impeding the oxygenation of the blood, and being, in consequence, attended with a peculiar claret colour of the pustules. The other mucous membranes—as those of the alimentary canal, bladder, vagina, urethra, &c. are incapable of taking on the variolous action; but in the larynx it sometimes runs so high as to produce sloughing—a specimen of which the Doctor exhibited. Even the eye, which so frequently suffers from small-pox, Dr. Gregory affirms to do so from common inflammation only; the pustule on the cornea not appearing till the eruption is on the decline, and therefore not being a primary or essential feature of the disease. This form of small-pox is very fatal; the eighth and ninth days being those of danger.

4. Some persons, especially those liable to cerebral affections, die at an earlier period—generally *within* the first eight days. These cases are ushered in by fierce delirium, succeeded by symptoms of effusion into the brain. Corresponding appearances present themselves on examination after death. To this variety the Doctor gives the name of *nervous* small-pox; and he believes it to depend, not on inflammation, but on a specific or *variolous* action. That it is not, strictly speaking, inflammation, is rendered probable by the fact of the blood, when drawn at this time, not exhibiting the buffy coat, and by the little benefit derived from blood-letting.

5. The last variety is regarded as depending on the *dissolution* of the blood—marked by petechiæ, passive hæmorrhages, &c. From this Dr. Gregory never saw any patient recover who was not guarded by previous vaccination.

Rather an animated debate followed, the general result of which was, that most of those who had seen any thing of small-pox recognized the divisions proposed by Dr. Gregory as correct, and leading to useful practical consequences: still they were not admitted as distinct *species*, nor as having their seat in essentially distinct tissues—or, at least, when any besides the skin and mucous membranes were affected at all, such affections were held to be only common inflammation.

HOSPITAL REPORTS.

ST. BARTHOLOMEW'S HOSPITAL.

Case of extensive Inflammation and Suppuration of the Thigh, following Wound of Knee-Joint.

HENRY PHILLIPS, æt. 40, admitted into Pitcairne's Ward, under Mr. Earle, Sept. 13th. This patient, six weeks previous to his admission into St. Bartholomew's Hospital, had inflicted a wound on the inner and front part of the knee (which penetrated into the joint, dividing the integuments to the extent of two inches), while engaged in shaping the spokes of a wheel with a drawing knife. He was immediately conveyed to another institution. Extensive inflammation of the knee and thigh followed the receipt of the injury, which was not checked by the application of leeches and cold lotions, and in about a fortnight matter had formed in the upper and inner part of the thigh, for the discharge of which a small inefficient opening was made with a lancet. A thinish pus continued to drain both from the artificial opening and from the original wound in the knee-joint, reducing the patient considerably; the integuments of the thigh acquired a very firm resisting texture, which went on gradually increasing; the accompanying debility became daily more manifest, alarming the patient for his safety; and at the end of six weeks he grew dissatisfied with his treatment, and, worn out with continued pain and mental anxiety, he was conveyed home, and placed himself under the care of a private practitioner. The gentleman who visited him, not feeling quite satisfied as to the nature of the case, and wishing for further advice, Mr. Earle was called in. The state of the patient at this time was as follows: Reduced almost to the last extremity, with a pulse small, thready, and scarcely to be felt; the whole body bathed in a cold clammy sweat. Mr. E. believed him to be in articulo mortis. The integuments of the thigh presented a perfectly firm, horny, or cartilaginous feel, not in the slightest degree yielding to the

pressure of the finger. There was at this time little discharge from either wound. Mr. Earle felt assured of the presence of deeply-seated matter, and of the necessity for its immediate evacuation. Nothing like fluctuation could be discovered through the hardened integuments. Mr. E. had not been apprised of the nature of the case, and was provided at the time with no other instrument than a common bleeding lancet: with this, however, an incision was made about six inches long, extending up the thigh. The lancet was first thrust directly downwards, till the shoulder was buried, and not till then did it reach the depôt of matter. The instrument was then carried upwards, cutting its way out with considerable difficulty, owing to the firm resistance offered by the horny texture of the parts. Another cut was made to communicate with a former opening. Matter followed in the whole track of the incision, and in this way a large quantity of sloughy portions and of sanious foetid fluid were evacuated. He was directed to take Carb. ammon. gr. v. 3tis horis, and lint was introduced into the wound. The patient felt relieved soon after; the pulse became more distinct; his feelings of alarm and nervous sensations gradually left him, and he felt more composed than he had done for some time previously. Mr. Earle had him removed to St. Bartholomew's Hospital, September 12th, where he continued gradually to improve. The hardened state of the skin and cellular tissue slowly disappeared, and with the use of quinine his strength was restored sufficiently to enable him to leave the hospital October 8th, with very good motion in the knee-joint, and feeling very grateful for what had been done for him.

Case of large Scrotal Hernia, reduced by general means.

John Ross, æt. 28, admitted Sept. 17th, into Powell's Ward, under Mr. Earle, with a large scrotal hernia of the right side. The man states, that, two years since, he ruptured himself while lifting a heavy weight. He felt something to give way at the time, and observed a swelling in the groin, which gradually increased, and descended into the scrotum. For the space of about two years he suffered no inconvenience from the rupture, which was always protruded during the day, and returned again upon his going to rest at night. During this time he never wore a truss. About three weeks before his admission, he found that he was unable to return the hernia as usual. He states, that, from this time, the swelling gradually increased in size, the scrotum being much more distended than he had ever observed it to be before; and its friction against the thighs causing him much uneasiness and pain, he was induced to seek relief

at this hospital. When admitted, the scrotum was found to be considerably distended with a hard and inelastic mass, which was supposed to consist of omentum; the testicle could be distinguished at the most inferior part of the scrotum; bowels not constipated. The protruded parts firmly resisted any attempts at reduction by the taxis; and as there were no urgent symptoms, it was resolved to give the emaciating plan a fair trial, with the view of lessening the bulk of the tumor by reducing the quantity of fat of which it was thought chiefly to consist. As Mr. Earle expressed it, he would try to convert his fat into soap, by the internal exhibition of the liquor potassæ.

The patient was put upon low diet, and the recumbent posture was strictly enjoined. He was ordered to take liq. potass. ℞ ter die; and with the view of assisting the absorbents, the unguent. hyd. was directed to be rubbed in so as to produce slight ptyalism. The good effects of the treatment were in a short time manifest, and at the end of five weeks the plan had succeeded perfectly. The hardened omentum gradually softened and decreased in bulk, until it was entirely reduced. The neck of the sac was felt to be considerably thickened. October 24th he was ordered to have a truss, and discharged on the 27th.

Luxation of the Thigh Bone upwards and forwards on the Pubes.

Mary Hinds, æt. 63, was admitted into this hospital October 19th. She said that she slipped down stairs and fell on the right hip, with the leg under her. The dresser was not able to ascertain exactly the nature of the accident, but recognized the head of the bone, which obeyed the motions of the limb, in the groin. Mr. Vincent saw her on the 20th, and shewed the case to Messrs. Lawrence and Earle, when it was decided to be a dislocation upwards.

On examining the limb, it appeared about two-thirds of an inch shorter than the other; the toes everted and pointed downwards, so as not to allow the heel to reach the ground; the knee was also everted; the heel and knee could be brought close to the opposite limb; the femur was not bent either backwards or forwards with regard to the pelvis, and could easily be flexed to a right angle with the pelvis; it could not be rotated inwards, and but slightly outwards; by using a slight extension, the limb could nearly be brought down to its original length; the hip was flattened externally. Situation of the head of the femur, upon and rather to the pubic side of the inferior, anterior, spinous process of the ilium, having no muscle between it and that process; in front, and covering that part of the head nearest the neck, was the origin of the rectus muscle that arises from the inferior spine; external-

ly and laterally the origins of the sartorius and tensor vaginæ femoris, which crossed the neck; on the pubic side, and rather in front, were the iliacus internus and crural nerve; the psoæ muscles and vessels still more internally; above was the crural arch; the origin of the rectus appeared the chief obstacle to still greater shortening of the limb; there was no pain or numbness from the pressure on the nerve when the limb was at rest.

Reduction was first attempted without the assistance of pulleys, the woman lying on her back, and extension made in a line with the body; but as this plan did not succeed, she was placed on the sound hip (the left), and the pulleys applied, using extension in a direction posterior to the body. Mr. Earle at the same time pressed down the head of the bone, by which means the reduction was effected in eight minutes.

The age of this woman caused suspicion of fracture of the neck of the bone. The limb was not in this case flexed either backwards, as mentioned by Boyer, or forwards, according to Sir A. Cooper's authority, by reason of the small size and weakness of the muscles of the patient. The only diagnoses between this accident and fracture of the neck, were protuberance in the groin obeying the motions of the limb, and inability to rotate the limb inwards.

Two similar accidents have occurred at the Manchester Infirmary within the four last years, the latter within ten months: in both of these the thigh was flexed on the pelvis. Another case was recently admitted into an hospital in Dublin.

GLASGOW EYE INFIRMARY.

Traumatic Cataract—Spontaneous Cure.

GEORGE ROBERTSON, æt. 11, Feb. 20th, 1829. Fourteen days ago received a blow on the right eye from a stone. It has been followed neither by much pain nor inflammation, but the lens is almost completely opaque, and appears in contact with the iris. There is a small, opaque, elevated spot on the cornea, apparently the result of a wound. Vision gone, except mere perception of light and shadow. Belladonna applied externally, and Epsom Salts given internally.

March 6th.—Conjunctiva slightly inflamed.

Gutta solutionis nitratis argenti.

13th.—A small fragment of the lens has fallen down in front of the iris.

16th.—More of the cataract fallen down in front of the iris.

Sept. 19th.—Lens dissolved. Some small shreds of capsule still in view. Pupil lively. Eye strong; and, with a two inch and a half convex lens, can read a large type.

Fistula Corneæ.

William Garth, æt. 19, 4th March, 1829. Fifteen years ago, the lower part of the left cornea was penetrated by a fork, which had also injured the iris; bringing on iritis, contraction of the pupil, and adhesion of the iris and capsule of the lens. At present the cornea around the place of the puncture is in a state of ulceration, and appears to have been bathed with a solution of sugar of lead. Close to the inner and lower edge of the cornea there is a vesicular swelling, almost the size of a split pea, which appeared about ten days ago. This was punctured, and a fluid issued from it.

6th.—Gtt. Sol. Nit. Argenti.

9th.—Vesicle has filled again, and again punctured.

11th.—Vesicatorium pone aurem sinistram.

16th.—Vesicle again filled. Zonular sclerotitis.

Cap. Pil. Calomel. et Opii, i. omne nocte.

30th.—Vesicle much enlarged. On snipping it off, it is evident that there is a communication with the anterior chamber.

A pencil of nitras argenti to be applied to the fistula.

April 1st.—Appearance of a new vesicle very minute and close to the edge of the cornea.

8th.—No appearance of the small vesicle growing.

May 4th.—Inflammation increased.

Adhib. Hirudines, vi. temp. singulis. Vesicator. pone aur. Contin. Pil. Cal. et Opii.

11th.—Pain nearly gone. Still considerable vascularity of conjunctiva.

Utatur Collyr. Mariatis Hydrarg. (a grain to 8 ounces).

12th.—Mouth slightly affected.

Sum. Pil. 2nd qq. nocte tantum.

20th.—Eye easier. Continue the pill.

June 6th.—Pain almost gone. Omit Pil. Cont. Collyr.

Sept. 19th.—Eye, for the last six weeks, quiet. Pupil completely closed. Iris in contact with cornea. Specks in the same state as at admission. Fistula of cornea completely gone. Distinguishes light and shadow. Dismissed relieved.

NOTICE.

We wish to hear again from B.

ERRATUM.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

LECTURE VIII.

Treatment of Inflammation.—Bleeding.

WHEN I spoke to you, gentlemen, in my last lecture, of disorder of the digestive organs, and of that state of the system which Dr. Barlow would have called plethora from defective secretion, I should have stated to you that, although the most common cause of this condition is excessive nutrition, or errors of diet, yet that it may occur independently of these, without any excess, and, in fact, without any imprudence in the mode of living. It may take place in consequence of certain circumstances which act immediately on the nervous system, and which affect the digestive organs secondarily.

Among the causes which are referable to this head we may mention neglect of exercise, indolent habits, sedentary pursuits, residence in the impure air of confined and crowded dwellings, excessive mental exertion, and long-continued anxiety, or affliction: all these are causes which act *primarily* on the nervous system, and which disorder the digestive organs through that medium. We see many instances in females, and often in males also, where the condition of the constitution that I have described takes place, and in which we cannot trace it to any thing like excess, or imprudence; and in such instances we are, in general, able to refer them very clearly to causes of the nature just mentioned.

I shewed you, in my last lecture, that the state produced by a considerable local injury is capable of leading to serious inflammatory disturbance in various important organs at a distance from the original affection; that the state of system arising in con-

sequence of a compound fracture, or other extensive wound, laceration, or bruise of a part, may cause inflammation of the peritoneum, pleura, pericardium, lungs, heart, liver, or spleen, as well as of the joints, and various parts of the muscular system. If, then, such important and serious symptoms can arise in the parts now mentioned, in consequence of the active disorder excited in the system by any considerable local injury, you can easily suppose that the less violent disturbance, which constitutes plethora, may be capable of producing the various local inflammations, or other diseases, which are supposed, in common language, to originate spontaneously, or of themselves, and which have given so much trouble to nosologists, in order to account for their causes and the mode of their production.

I proceeded, in the next place, to speak of inflammation, adverting first to the disease in its acute or active form, whether it occurs with or without fever. In the view which I have already had occasion to give of the disorder which constitutes inflammation, I have shewn that this is a temporary state of the part—that is, that the condition of inflammation may arise, may proceed to its full development, may then decline, may entirely disappear, and leave the part in its natural or normal state, so far as regards its functions and structure, without any treatment at all. In this respect there is a striking contrast between inflammation, and the changes of structure which occur in those affections which are denominated *specific*—those *organic* changes, as they are commonly called, such as cancer, fungus hæmatodes, and so forth; for in alterations of this nature the change seems to be essentially destructive. These alterations are so destructive to the part in which they occur, as to render it unfit for the accomplishment of its destined purposes, and they proceed till they entirely destroy the parts in which they take place. Hence has arisen the term which has been given to this peculiar kind

of change—*malignant*. But inflammation, on the contrary, seems to have a natural tendency to terminate in a state in which the part is again left capable of exercising its proper functions.

We must observe, however, that inflammation, when it is violent, dangerously disturbs, or even entirely suspends, the function of the organ in which it takes place; consequently it is absolutely necessary that it should be quickly arrested, when it affects any part of which the continued action is necessary to life—such as the brain, the heart, or the lungs; the larynx, stomach, or intestines; and the contents of the cavity of the abdomen generally. When inflammation affects any of these viscera, it is quite possible that, if the action of the part could be dispensed with for a time, the inflammation might go through its course, and leave the organ in a state capable of exercising its functions afterwards: but the danger here arises from the want of the due performance of the function during the time that the inflammation is at its height. The regular exercise of the organ cannot be dispensed with, for carrying on the purposes of life; therefore you must stop the inflammation, to prevent the effect which would otherwise be produced in the economy, by the want of a certain effect which is absolutely and indispensably necessary.

Again, the various effects of inflammation—particularly mortification, suppuration, and interstitial deposition—are capable of producing such changes in the state of the organ as to render it in a greater or less degree incapable, after the inflammation has ceased, of carrying on its regular functions: even the least important of those terminations—interstitial depositions—are capable of producing changes in an organ which will seriously and permanently impair its action. Such deposition will thicken and harden a part; it will consolidate structures that are naturally loose; it will unite those that ought to be free and distinct; it will render opaque, parts that are naturally transparent. Those various changes may arise in consequence of inflammation—not of the very highest degree: when, for instance, it occurs in a joint, induration and thickening may take place and produce a stiffness of the parts, thus rendering the limb incapable of executing many of the motions which properly belong to it. Or suppose inflammation occurring in the eye, or in the ear, parts of the utmost importance, a comparatively low inflammation will here produce such changes as will afterwards seriously impair the functions of the parts. Suppose you have inflammation in the cornea, in the iris, or in the retina—the disease may go through its stages without producing any very serious symptoms, or any very considerable sympathetic effects on other

parts of the economy; but you find, in the first instance, that interstitial deposition will take place in the cornea, which will obscure the aperture of the pupil, and render vision imperfect; in the second instance you will find, if lymph be effused upon the iris, it will cause it to adhere to the capsule of the chrystalline lens, and thus impede or actually destroy the sight; you will find that the dark structure of the retina may be thickened and rendered opaque, and thus disabled for the execution of its proper functions; and therefore, in consequence of these several changes, according to the degree in which they take place, the vision will be more or less considerably impaired. Suppose you have inflammation affecting the hand or foot, and that it proceeds to suppuration—you will find afterwards, that the skin will be rendered adherent to the tendons, and these will become agglutinated to each other. Perhaps one or more joints will suffer suppuration; and the consequence will be that the hand or the foot will have a motion so far imperfect as to render it of much less use than in its natural state. Thus, although the part affected by inflammation may not be essential to life, it is nevertheless necessary to adopt active measures, in order to arrest the diseased action, for the purpose of preventing those changes that would *subsequently* interfere with the functions of the part; and if you are to accomplish your object, you will find it necessary to use means quite as active in the one case as in the other—that is, treatment quite as diligent to stop inflammation in the joints of the hand, or foot, as if it were seated in the heart, the lungs, the stomach, or the intestines.

Farther—although inflammation should not be seated in a part which is immediately important to life—although there should be no immediate danger of consequences that would be seriously injurious to the function of the organ, yet it is a matter of great importance to arrest the inflammatory process for this reason—the longer the vessels of a part remain overloaded, with the more difficulty do they recover their natural state, and the more easily will they become again distended. The continuance, therefore, of inflammation, increases the difficulty of recovery, and the liability to relapse. Hence it happens that organs that have once been inflamed much more easily become so a second time; and the danger of a subsequent occurrence of inflammation is in proportion to the degree of the disease that occurred in the first instance, and to the length of time it has been allowed to go on. Persons who conduct the business of life assurance are well aware of this fact:—when any one wishes to insure his life, they enquire, not only whether the individual is healthy at the time that he makes such proposal, but they institute a

careful scrutiny into the state of the applicant's health in the *preceding* periods of his life—they enquire whether at any time he has had a serious disease of any kind, and if they find that he has, although he may be healthy at the time, they commonly refuse to insure his life—they consider such person to be an unsound man; and in fact if inflammation in a particular organ has taken place, there is a considerable danger of such inflammation occurring again.

Besides, in the treatment of inflammation, we are not entirely to overlook the advantage to the patient that is derived from immediately relieving him from a condition of considerable suffering. In a case of acute local inflammation, accompanied with high constitutional symptoms, this is a circumstance of no trivial importance: the local pain, and the suffering arising from general disturbance, are so great, that it is a matter of considerable moment to relieve a person from it as quickly as possible.

There are various active measures of a preliminary and auxiliary kind which are of great use, and which, although they do not immediately tend to subdue inflammation, nevertheless place the patient under a state that is favourable for the action of more direct means. In the first place, you must remove the cause of the inflammation, provided it be of a nature to allow of this: if there be a foreign body in contact with the surface of the eye—if the patient have been exposed to the application of cold—if he have suffered from insufficient clothing—these are circumstances which you can remedy or entirely remove. In respect to the position of the part which is the seat of inflammation, you must place it under such circumstances as will be most favourable to the return of blood from it. We often find in such cases, that the condition of the organ will be very materially affected by the position: if it be in a situation unfavourable to the return of the blood, the vessels will be distended, the part will become red, and considerable pain will be experienced. In a case where any part of the head is inflamed, therefore, you would have to elevate it—you must not allow the patient to lie with his head low. In a case of inflammation affecting any part of the lower extremities, you would have the patient placed in a horizontal position, and you would keep the part that is inflamed in a state of rest. The natural execution of the function which belongs to the organ would be a source of considerable excitement to it when suffering under inflammation; therefore, absolute repose of the affected organ is a circumstance generally necessary. For example—you would not allow a patient to use an inflamed joint; or if the eye were inflamed, you would not suffer the patient to exert it. Supposing the head

to be the seat of the disease, you would not permit the active employment of the mental powers by attention to any complicated matters, or by intense study. A general repose of the whole frame is equally important where an organ of consequence is the seat of inflammatory disease; and, in fact, the recumbent posture of the entire body is very favourable to the process of recovery from such inflammation. We find the pulse becomes considerably reduced when the body is placed quietly in a horizontal position. You would endeavour to remove all those local circumstances that are capable of exciting the inflamed part: all external pressure of clothes, or any thing else, should be avoided. Hence the medical attendant ought only to examine the diseased organ so far as it may be necessary to ascertain its exact state—pressure, and the various efforts that are made in such an examination, are causes of excitement that should be avoided as much as possible—we ought to feel for the circumstances of the sufferer. The patient who is labouring under any kind of inflammation should occupy a large airy apartment, the room should be well ventilated, and his dress or his bed-clothes should be light, and no more than sufficient to keep him in a comfortable temperature. These are circumstances of general operation.

When we come to consider the positive means by which inflammation is to be reduced, our first view is directed to the taking away of blood. This is the most important measure by which inflammation can be attacked; blood is, in fact, the material by which the increased action of the part is kept up. If we may be allowed to use figurative language, the obvious increase of heat in the part is analogous to that of fire, and blood is the fuel by which the flame is kept up; in fact, if we could completely take away its blood from the part, we should be able entirely to control or arrest the increased action. Loss of blood, then, is the most powerful means for arresting the increased local action, and for quieting the general disturbance which is the consequence of this. All other means are of minor importance—this is the great remedy on which we have to depend in diminishing and removing inflammation.

Bleeding is either *general* or *local*. In *general* bleeding, the blood is drawn from a large vessel by a single orifice: it may be taken either from a vein or from an artery. In the former case, the process is called *venesection* or *phlebotomy*; and in the latter case it is called *arteriotomy*.

When blood is taken from a vein in a case of decided inflammation, we very commonly find that it presents a peculiar character—that it is different in appearance from that of an individual in health: we find that the

blood coagulates slowly, and consequently that the red particles sink in the clot or crassamentum, so as to leave the upper part of this free from the colouring matter. The upper part of the crassamentum of the blood thus presents fibrin or coagulated lymph in a pure state, free from red particles—we find that it has a yellowish appearance, that it presents what is called a *buffy coat*, and very commonly that it coagulates more considerably than under a natural state, so that the superior surface of the clot has a concave figure—that is, in common language, it is *cupped*. The blood, then, drawn from a patient labouring under inflammation, is commonly said to be buffed and cupped; the surface of the crassamentum being of a light yellowish colour, in consequence of the precipitation of the red particles, and being drawn together, so that it assumes the appearance of a cup. I say, this is the appearance the blood presents when taken from the vein of a patient labouring under inflammation; and you will naturally enquire whether it is not also the appearance of the blood drawn from an artery. Now the truth is, that the practice of drawing blood from an artery is by no means so common as that of venesection, and therefore it is difficult to determine whether the arterial blood presents the change which we have just described, nor do I know that I ever had an opportunity of ascertaining the point exactly; but my friend Dr. Tweedie has given me a statement of two instances in which he has found the blood drawn from the arteries to present the same character and appearance which is seen in that taken from the veins. I will just read to you the note that he has made of these cases. He says—"When I was house-surgeon at the Infirmary in Edinburgh, I was directed to bleed a patient under the care of Dr. Hamilton, afflicted with hæmatemesis (vomiting of blood): the general febrile symptoms were very severe. I attempted to take blood from the veins of the arm; but, from their small size, I could not obtain the quantity ordered. I then opened the jugular vein, but in consequence of the struggles of the patient, the orifice closed. I next opened the temporal artery, from which the blood came in a full stream. The blood soon coagulated, and, to my surprise, I found that it presented a cupped appearance. I shewed the blood to my friend Dr. Gordon, who told me that he had searched every where for such a specimen, and that he had written to the surgeons of the large hospitals in London to know if they had observed such an occurrence, and their answer was in the negative. It is now in his museum. I have since had an opportunity of observing the same thing in a patient of mine in the Fever Hospital, who was bled in consequence of inflammation of the brain under fever. This specimen

has since been sent to Mr. Grainger, who has alluded to it in his work on General Anatomy."

When we speak of blood exhibiting an inflammatory character, we allude to the two appearances that I have now mentioned; this buff colour on the surface of the coagulum, and this cupped appearance or concavity.

In local bleeding, the blood comes from the capillaries; it is drawn from a great number of openings in the minute vessels of the part. Blood, in this way, is taken from a part by cupping; by the application of leeches; by scarification, or by punctures. Now cupping seems to form a kind of intermediate mode of taking blood. When blood is drawn by cupping by a person who performs the operation skilfully, it differs but little from general bleeding. A skilful cupper will take twenty ounces of blood from the back of the neck as quickly as you can draw it from the arm; therefore we cannot suppose that there is any material difference between the two cases in their effects upon the system. In certain instances of cupping we cannot say that the blood is taken simply from the capillary vessels. I have seen cupping performed where arterial trunks have been divided, which have thrown out their contents in jets, three or four crossing each other in the cupping glass. When it is performed well and rapidly, I do not see the difference between the abstraction by venesection and cupping—though in the one case it is called local, and in the other general bleeding.

In this country, in general bleeding, phlebotomy or venesection is most frequently practised on the arm. The blood is taken from one of the veins at the bend of the elbow, that being found to be the most convenient situation; but on the continent, venesection is practised on the veins of the lower extremities, particularly those of the foot and leg: and the physicians and surgeons of France seem to consider that peculiar advantages arise from taking the blood in this manner under certain circumstances. They think, for example, that it is more efficacious in affections of the head. They imagine that *derivation* from the head takes place. This is a kind of scientific word, which I believe has not a very definite meaning; and, in point of fact, we have no direct evidence to shew, that in cases of inflammation, it is of material consequence whether we take blood from the veins of one part of the body or of another. Hence we come in this country to practise general bleeding from the arm, on account of a conviction that if blood be abstracted, it is of no consequence from what vein it is taken.

Since, then, there are these two modes of taking blood, viz. general and local, a ques-

tion will naturally arise—what are the cases in which the one or the other is preferable? What quantity of blood should be taken? How often it should be repeated? And what is the comparative efficacy in respect to reducing inflammation between the abstraction of blood, and the other means by which the same purpose may be accomplished?

When you hear of local bleeding, you perhaps are inclined to suppose that it would be a proper mode of attempting to reduce every inflammation. You would imagine that the best way of reducing increased action in any organ would be to take blood from the part itself; to take away from the organ that is the seat of excitement—the material which keeps up that excitement. You would therefore suppose that local bleeding would be the most direct and powerful means of reducing any local excitement. This, however, would be an erroneous conclusion. You can take blood out of a part by local bleeding, but you cannot stop the supply which goes to it. You can take away a portion of the blood that is in it, but the blood still continues to come. The question, therefore, is, how you can cut off the supply of blood from the inflamed part? This is necessary, to arrest the disturbance in the organ, and it can only be accomplished through the medium of general bleeding. If you carry general bleeding to a sufficient extent, you can entirely stop the increased action in any part, and you cannot do that by local bleeding.

Take the case of a patient labouring under inflammation of the chest. A person has a violent pain in the side; he is unable to distend the thorax fully; in short, the inflamed organs are in such a painful state that he cannot use the voluntary exertion that is necessary to fill the lungs with air. You find, along with this, heat of skin, and a state of general distress. You open a vein in the arm, and take away a considerable quantity of blood; and when you have done this, you find that the reduction of the circulating fluid will enable the patient to distend the thorax with facility; he can take in a full and deep inspiration; and the general distress that previously existed is completely removed. This will more particularly be seen if you carry the abstraction of blood so far as to produce fainting. You find that a change in the state of the respiration is produced immediately; you see the effects even while you are drawing the blood. Thus you have a clear proof that this mode of relief is capable of putting an end to the local increased action which inflammation of the pleura or lungs produces. Suppose, now, you bleed a patient labouring under considerable inflammation of the eye. You see a preternatural redness of the organ; you find that there is a great deal of pain

in it; that the patient is unable to open it against the light; that it is suffused with tears; and that any occasion to use it produces an overflow of these on the surface of the cheek. You take a good quantity of blood from the arm of the patient, so as to produce a state of fainting; immediately, and before your eyes—for you can see all the phenomena here—you observe that the part, which was of a bright colour, becomes quite pale;—the capillary vessels of the organ are emptied: in fact, you find the patient can open the eye with facility to the light, and for a time the part has passed nearly into a natural state from one of violent inflammation. You see in both these instances that the abstraction of blood generally is not only capable of checking the inflammatory process, but, for the moment, of entirely removing it. It is true that in the one case, and in the other, the inflammation will in some degree recur after the loss of this blood, but it never comes back with the same degree of violence. The effect you produce in inflammation by the free abstraction of blood—from the system, is to diminish the increased action, which never resumes its former intensity.

General bleeding, then, is necessary in inflammation of any organ important to life, such as the brain, lungs, liver, and other parts that I have formerly enumerated. It is also necessary in the case of inflammation of any organ where you suspect the probable occurrence of those changes of structure that would subsequently impair the functions of the part. Thus free abstraction of blood is necessary in inflammation of the eye, or of the ear; in inflammation affecting the hand or any important joint of the body. General bleeding, again, is necessary in serious injury of any important part, or where the injury is of considerable extent, even though it does not affect a part of importance in itself, because we know by experience that injuries of this sort will produce inflammation. We know that inflammation arising under such circumstances will be attended with considerable constitutional disturbance; and therefore the common sense of mankind, independent of the medical class, has led them to know that persons who receive injuries, such as those alluded to, ought to be bled, as forming an impediment to the actual occurrence of inflammation. Now some persons have held, that under such circumstances you ought not to bleed till inflammation has come on; that you should wait till the disturbance occurs, and that you should then take the means necessary for removing it. I cannot, for my own part, at all accede to this opinion. We know that in the laws of sporting, when a fox is started, or a stag is turned out, they hold it entitled to a certain time to make its way; this sportsmen consider as a settled law, but I do not think that we are

bound by any of these rules in respect to inflammation. We ought not to consider it a point of honour to allow inflammation to go to a certain extent before we attack it. I think we may safely take means to prevent the disturbance; and, therefore, when a serious injury takes place, more particularly in individuals of robust habit, and at an age in which inflammation is likely to occur, we should adopt the means necessary to prevent the occurrence of inflammation, which we know by experience will take place unless we do so.

It would be a desirable thing for us to lay down a rule, if we had any means of doing so, by which we could determine in all cases where general abstraction of blood should be had recourse to, and where we might be contented with local bleeding; but I rather fancy we should hardly be able to find any such general criterion. If that constitutional disturbance exists which constitutes inflammatory fever, we may safely bleed *generally*, but then we cannot say that if it is absent we should therefore be content with bleeding *locally*. There are many instances of local inflammation which require active means to arrest them, but in which a febrile disturbance of the system is not present. You may have an inflammation of the eye, which will require bleeding of the most active description, but in which there is no fever. We may say, therefore, that the existence of febrile disturbance justifies general bleeding, but its absence does not render it apparent that we should be contented simply with local bleeding.

Then supposing that we deem it necessary to have recourse to general bleeding, what is the mode in which we should employ this evacuation? Are we to take a large quantity of blood, and to endeavour, by one copious bleeding, at once to put a stop to the inflammatory action, or are we to take a smaller quantity of blood, and to repeat it? It is matter of question between a considerable and free venesection, and a repeated smaller loss of blood; and I may mention that it is more common in this country to take a large quantity of blood at once; but I believe it is more the practice, in France, Italy, and Germany, to take a smaller quantity of blood at a time, and to have recourse to more frequent evacuations. I have no hesitation in saying that the preferable plan, because the most efficacious, is that of taking such a quantity of blood as shall produce a decided effect on the circulation at the moment; that is, you are to apply a large bleeding as early as you can in the affection, and this is not to be measured, as to its amount, by the mere number of ounces. You cannot say that ten, twelve, or sixteen ounces is sufficient, but the quantity must depend on the effect produced. You are to bleed until you can reduce the state of excitement which

exists in the system, and you must carry the depletion to whatever extent is required to produce this effect. It may be necessary to take 20, 30, or 40 ounces of blood; and if, without the patient fainting, you cannot make a decided impression upon the circulation, you must go to that extent. It has often been said that you will weaken a patient very much by taking this quantity of blood; certainly, for your object is to weaken the patient. You consider that in this respect he is too strong; that he has got too much blood, or you would not take it from him at all. Your object is to weaken the patient, but undoubtedly you would wish to put an end to the inflammation by producing as little subsequent debility as you can; and I think the object will be best accomplished by taking such a quantity of blood as will decidedly influence the state of the circulation. It appears to me, when you take a small quantity of blood, and proceed taking it three times a day, or as frequently as you can, that you bring the patient ultimately to a much weaker state than if you took a large quantity at once. In short, if you take a large quantity at once, you do not want to bleed again; whereas, in the other case, you take blood day after day, and continue it for some length of time; and I have no doubt of being accurate when I state, that the plan of small bleedings accomplishes the object ultimately at a much greater expense to the constitution than if you take a large quantity at once.

Some years ago I had occasion to attend a young female—a slender girl—for a serious attack of inflammation of the chest. I bled her not very sparingly, and adopted other suitable treatment. I found it necessary to repeat the bleeding several times, and notwithstanding a considerable number of bleedings, the inflammation was not satisfactorily reduced. The symptoms in the chest continued, and I deemed the patient in danger; but her circulation was at last reduced to that state that I could not take more blood. I then resorted to digitalis, and either through the means I employed, or through her possessing a good constitution, she got over the complaint and recovered. It happened two or three years afterwards that I had occasion again to treat her under an attack of a similar nature. I was requested to see her, she being employed at an institution with which I was connected. The week before this occurred she had wanted a tooth extracted, which I removed for her: this was attended with great swelling about the jaw, so that I found it necessary to employ a great number of leeches, and take blood from the arm. At the end of the week in which these means were resorted to, I found her labouring under symptoms of the highest degree of inflammation in the chest; and although she

had only been attacked a few hours, the symptoms were of the most strongly marked kind. She was in excessive pain, and could not speak to me. There was great heat over the whole body, a white tongue, and a highly disturbed state of the pulse, which was full, strong, and very frequent. I never saw symptoms so intense brought on in so short a time; but the case was very favourable for making a decided impression, as the attack had only come on a few hours before, and I therefore bled her from the arm. She was, as I have already said, rather slender, or what we would call a weak young woman. Nevertheless, the blood spirted out most vigorously from the opening when it was made, and then flowed very freely (in cases of inflammation when the blood runs freely, I go on till it stops, for that is the only way to do good); and I got a large vessel, intending to make her faint, for I thought if it produced that effect upon her it would stop the inflammatory process. But to my astonishment she did not faint, and the blood proceeded pouring out of the arm in a vigorous stream, without running over the integuments; till at last I stopped, because the quantity taken was so considerable. I had the blood weighed, and it was found to be three pounds—that is, 48 ounces. I believe it was an ounce or two more: and yet this large evacuation did not make the young woman faint. Now that single venesection cured her, so that she was well from that time; all the symptoms were removed, at least she had no farther sign of inflammation of the chest. She was kept quiet for two or three days, and restricted to low diet: but I may say that she required no farther treatment than that single free venesection.

In those cases in which there is sympathetic inflammatory fever—that is, in which the digestive organs are disturbed, and in which the secretions are suspended—it is found, that when the secretions return, and when the digestive functions are restored, the fever is diminished, or stopped; and thus it is said that the restoration of the natural secretions removes the fever. Yet, perhaps, it might be more correct to say that these secretions return because the fever is removed. However, pursuing the analogy, many persons say, do not bleed patients that are so situated; attempt to produce depletion by aperient medicines—make the bowels act—give remedies that will reproduce the discharge from the skin, and thus you will get rid of the fever. Now the truth is, if you carefully read the history of cases treated in this way, you will find that one, two, three, or four days are employed in evacuations of this kind. Purgative medicines are given which do not act; diaphoretics are tried which produce no discharge from

the skin; while the local inflammation goes on increasing, and the general disturbance gets worse and worse; till at last, by evacuations, and the return of secretion, relief is obtained. Now it appears to me, that the treatment of inflammation by direct depletion, shews to great advantage when contrasted with the mode of treatment to which I have just referred. If you take a large quantity of blood from the system, you produce immediate and decided relief; and, in fact, you find that those objects which you are endeavouring to attain by medicines, and do not accomplish for a long time, are at once effected by the loss of blood. Very frequently, evacuation of the bowels comes on after a free abstraction of blood, particularly if you induce syncope; you also often find that the patient breaks out soon after into a profuse perspiration; the secretions that had been suspended having now been restored, in consequence of your taking away the load that oppressed the system. When this is relieved its natural actions go on properly; and thus direct depletion accomplishes immediately and at once that which, if sought for by indirect means, you do not attain for a considerable time: thus, too, we materially abridge the sufferings of the patient.

A notion has been entertained that persons who live in London, or in large towns, generally will not bear depletion—direct depletion—and that, therefore, the loss of blood which is proper in those who live in the country, is improper in the inhabitants of the metropolis or extensive cities. How this notion has arisen, or how it has become so general, I do not know; for I cannot conceive any thing more erroneous. In the inhabitants of London and large towns, we know that all kinds of luxurious indulgence which tend to produce a state of repletion in the system, are carried to a great extent. We know that sedentary habits are very prevalent, and, therefore, all the circumstances exist which are calculated to produce plethora—plethora of a serious nature—that state of the system in which high inflammatory action will occur, and, of course, in which it will require the most active and direct means for its control. I can only say that I am constantly meeting with patients residing in London who are in a state of local inflammation and general disturbance connected with it, that require the freest use of direct depletion, as I have now described it. I conceive, therefore, that the notion that a different plan of treatment is necessary in cases of the same disease occurring in the country and in London, or any other large town, is totally unfounded.

Another fear that has been entertained respecting the treatment now adverted to, is, that although it may be of efficacy in restraining the inflammatory action, yet the advantage is gained at the expense

of subsequent debility; that the patient will be weakened, and serious injury be done to the constitution, in consequence of the loss of blood. This is a fear in which I do not participate in the smallest degree. I do think there is a fear of debility from inflammation, but my fears point to that description of debility which results from the continuance of the inflammatory process—that subsequent weakening of the part which will be produced by those changes which inflammation is capable of causing in the structure of the organ. In both these cases, I think there is really ground for the apprehension of debility; but I have seen no reason to apprehend debility as the consequence of those means that are necessary to reduce such inflammatory action; so far otherwise, that I conceive the real and effectual way of preventing debility in such cases is, to adopt the most vigorous means for stopping inflammation in its early stage. It has been said that it will bring on typhoid symptoms. The words *typhus* and *typhoid* have become a complete bugbear; typhoid symptoms merely denote the state of an individual in whom certain organs are the seat of disease, and in whom the disease has gone to a considerable extent. Typhoid symptoms are by no means a necessary consequence of inflammation generally; they are merely one of the results consequent on disease existing in a certain set of organs—that is, in the nervous system. The only fear of debility in cases of inflammation generally is, that of allowing the disease to proceed unchecked, till it effects such changes of structure as will subsequently impair the functions of the part.

CLINICAL LECTURE

ON

DISTORTION OF THE SPINE.

By CHARLES BELL, Esq.

Professor of Surgery in the University of London,
and Surgeon of the Middlesex Hospital.

GENTLEMEN,

You perceive by the preparations around me the subject of my lecture; and whether it be strictly a clinical lecture or not, signifies very little. I have interrupted the regular course to take advantage of demonstrating to you, on the recent parts, the effects of lateral distortion of the spine. We have here a subject which exhibits the bones, cartilages, and ligaments of a young woman who had distortion of the trunk. These other specimens by my side are dry and rigid, but this is fresh; the cartilages and ligaments are entire, and the resiliency of the whole is perfect. I

have never had so good an opportunity of studying and demonstrating the principles which are to direct us in the treatment of this disease; and let me now tell you why I am so anxious for you to take advantage of this demonstration.

1. A mother, or a governess, brings a young lady to you for advice, observing that her shoulder is out—meaning that it projects further than the other one. Now, for the practitioner to be ignorant of the cause of this, shews that he has neglected a whole class of diseases; nay, more—that he has never been properly educated in anatomy at all. Yet I do assure you that I have had such patients brought to me, with the marks of leeches and blisters upon the shoulder, as if the joint itself had been in fault.

2. What think you, again, of condemning a young lady to lie in the horizontal posture for nine or twelve months for such a disease as this—the lateral distortion and twist of the spine? How lately is it that we had occasion to remark upon the aphorism delivered by Mr. Hunter, that the exercise of a part is necessary to retain the perfection of its texture. When you see the spinal column, consisting of bones with intermediate cartilages, with ligaments interlacing them, and numerous small muscles passing from point to point; and when you consider that these are tissues which will all degenerate from want of use—what can you imagine will be the effect of this column lying horizontally and unexercised for so many months, but the increasing weakness of all these textures? And, again, to see the young girl pale and feeble from long confinement, raised at last only by little and little, and suffering from faintness and palpitations of the heart; witnessing all this, what can you believe but that this treatment endangers the utter ruin of her constitution at her critical period of life?

3. Another error which may be committed is mistaking the distortion of the trunk for a consequence of curvature of the spine, when the spine only partakes of the distortion from a cause which is very different, and is very formidable. It happens in this way—a child has been seized with pneumonia, and has just escaped from the violence of the inflammation by the most decisive measures. She slowly recovers, but it is

found that she does not breathe with one side of her chest; the lungs have become consolidated by the inflammation; the ribs consequently remain in the state of expiration; they are huddled together, so that this side of the chest is about one-third of the size of the other; and the spine, you observe, must necessarily be curved, to accommodate itself to this condition. It will be in vain to attempt here those means of relief which are available in the proper case. I have an instance of this kind of distortion now under my observation, in a girl; and you see, in this cast, the peculiar twisted appearance which it gives to the adult.

4. But there is another case allied to this—I mean deformity from original malformation of the chest. The bones conform, in a very curious way, to the state of the parts which they cover: if there be no brain, neither is there a cranium; if the brain be imperfect, the imperfection is shewn in the cranium; and so in the thorax, the narrow and twisted chest is not the cause of disorder in the lungs, but it is the mark of imperfection in these organs. Sometimes we find that this imperfection is on one side only, and then the spine is distorted. This is an irremediable distortion.

5. Here is another circumstance requiring extreme circumspection. You see in these specimens that a callus has formed, which has united two or three of the vertebrae together, forming a sort of bony splint along the bodies. Now, in distortion, it is necessary to mark this well; and if, in examining the spine of a young person, you find that there is a curve towards the lower part of the spine, and that the vertebrae do not move at all, you must be very guarded in your practice. You must consider well whether previous inflammation has not had its seat here, causing the formation of such a callus; for it is possible that this interruption to the motion of the spine might be broken, and then there is reason to believe that the spinal marrow might be endangered by the communication of inflammation to it.

6. I have said nothing to you of the mistakes that are occurring every day, in confounding the scrofulous caries of the spine with lateral curvature. As to the case of distortion arising from *mollities ossium*, it takes place in the adult, and the symptoms are so marked that it can never be confounded with the cases which we are

about to describe. But rickets is a frequent source of mistake, and you must be especially careful, when consulted in a case of lateral distortion, to examine, by the means which I shall presently describe, whether the disease is in the spine and trunk alone, or is common to the whole bones, and attended with distortion of the ossa femora, tibiae, and pelvis. Enough has been said, I hope, to show that these questions must frequently come before you in practice; and now let me prove to you how satisfactorily we may draw our principles of the treatment of the lateral distortion of the spine from the study of the anatomy.

You observe, that when I place the bones of this trunk so as to rest upon the ossa ischii, the spine, whilst it is distorted in a very remarkable manner, possesses its elasticity, so that I can make the upper part of the trunk wave from side to side, the pelvis remaining stationary. This would imply that nothing should be more easy than to straighten the spine, or to undo this curvature, seeing that the chain of bones is

so very pliant. But in matter of fact it is not so : and when you look more minutely to the texture of the spine here, you will find that the distortion is not in the bones alone, but in the cartilages, the ligaments, and even the muscles ; for the muscles adapt themselves to the condition of the bones ; and therefore it is that nothing short of giving a new direction to the growth of the spine and all its connexions, will cure the lateral curvatures. You perceive, that by pressing on the left and lower part of the spine, and against the upper right side of the thorax, I can change the form of the spine from that resembling the italic S to the straight line ; but the moment I relieve the pressure, it resumes, by its elasticity, the curved position.

When a patient is brought to you, it is not unfrequent for the governess, or mother, to say, we observe the haunch on the right side (the superior anterior spinous process) to project. You see the reason of this ; for the spine ascending from the pelvis, as from a base, is inclined towards the left, and carries this part of the trunk off from that side of the pelvis.

In all these specimens and casts around me, you see that the first deviation of the spine from the straight line, at the lower part, is towards the left. I had occasion so lately to speak of the inclinations of the pelvis as illustrative of the diseases of the hip-joint, that you will easily follow me now when I speak of its effects upon the spine. The origin of the complaint we are treating of, is in the languor, relaxation, and weakness of a young girl. She has not that spring of health and vigour in her muscular frame to give a variety of exertion, and of position to her body. When standing, as they say in the north, she *hangs* upon her feet. I do not wish to vindicate this scotticism ; but to use a word not in your vocabulary, to distinguish what I mean from standing firmly on both legs. There is, you know, a provision in the lower extremity by which you can stand, resting yourself, as it were, and hanging on the ligamentous connexions of the limb, without muscular effort. A young person throws herself upon the right leg, as being the strongest, and the pelvis consequently drops towards the left side. The sacrum, which you may consider as the pediment of the pillar, being inclined, the whole column is thrown towards the left. The

first deviation being thus accounted for, we now inquire what is the cause of the second curvature of the spine. You will observe that the first position throws the weight of the body to the left side ; but that would be a most painful and irksome posture to remain in ; the person has, therefore, a disposition to relieve that constrained position by balancing the body ; and this cannot be done in any other way than, as you see here, by bending the spine towards the right side. There is a circumstance of some consequence to be noticed in the explanation of the further effects. We find that the young person who is distorted, stands mostly on the left leg. This is a consequence of her condition ; for, I have remarked to you, that standing on her right leg was the means she had recourse to at first, for relieving muscular exertion. Now the standing on the left leg facilitates the formation of the upper curvature of the spine, since it tends to bring the head and shoulders once more towards the left, and thus to be perpendicular to the line of gravitation of the body. Before we leave this subject, you will observe, that the spine is not simply inclined to the left, then to the right, and finally to the left again ; it is at the same time twisted ; and I must show you the effects of this spiral distortion on the hip and on the loins. The first effect is, a thrusting out of the hip and glutei muscles on the left side ; and the next is, a pressing out of the sacro-lumbalis and longissimus-dorsi on the same side ; for, you perceive, in the skeleton in my hands, how the transverse processes of the vertebræ of the loins are prominent on the left side, while those of the right disappear in this aspect, from being turned forwards. These processes, then, thrust out the muscles on the left side, whilst they admit of a concavity or flatness on the right. You will observe also that there is a prominence of the transverse processes in the dorsal part of the spine upon the right side, and a depression of them on the left. The effect of this twisting of the spine in producing a prominence of the long muscles of the loins on the left side is the first indication of commencing distortion, and is the last that disappears in the process of cure. We seldom see this first stage alone, because the mother's attention is not drawn to it before there is distortion of the upper part ; but when there is one of a family

distorted, producing an anxiety about the younger girls, you may then perhaps perceive in them that the disposition, which, if neglected, will produce distortion of the shoulders, has begun, and is exhibited in the unequal protuberance of the muscles of the loins.

Now let us attend to the effects produced on the ribs by this lateral curvature and twist of the spine. I demonstrate to you that the ribs on the left side fall together, or collapse; not only is there no proper space between them, but you see they hang over one another like the scales of armour; and the ribs on the right side diverge and bulge out. When I move the spine from side to side, you see that there is a mobility and expansion on the right side of the thorax, of which the left is not capable. Nor can you be ignorant of the cause of this; for if I represent with the chalk on the board the ribs going off parallel from the spine, right and left, the curve to the left side must huddle the ribs together on that side, and unnaturally extend or separate them on the other. Suppose I draw a line representing the curve in the dorsal vertebræ, and draw lines across this curve, always taking care that each line is perpendicular to the curved line, at the point where it crosses it: you see the effect—that the lines converge upon the left side, and diverge upon the right. The effect, you readily perceive, is a diminution of the convexity on the left side of the thorax; the false ribs also are pressed in upon the abdomen, and the margin of the chest approaches the ilium. As to the effect of the twist of the spine—it brings these false ribs of the left side too far back, and by a corresponding deficiency on the right side, produces a flatness on the lower part of the thorax, with an unusual gibbosity or projection on the upper part.

Observe now the effect of this upon the shoulders. The mother, drawing down the tucker of her girl, and exposing the lower angles of the scapulæ, holds her hands up in dismay, for she sees the right project at an acute angle, whilst the left falls down into the hollow of the side. You perceive, however, that the shoulders or scapulæ have nothing to do with the deformity—their position is consequent on the different convexities of the ribs on which they lie. The greater elevation of the ribs on the right side, and a certain projection of their angles, throw up the scapula

and shoulder, and elevate in an especial manner the lower angle, which again draws up the latissimus dorsi. The very reverse is the condition on the left side; because the scapula lies on the depressed and flattened ribs.

Now see, after this description, how you try back, as the sportsmen say. The mother brings her child with the right mamma and shoulder prominent: you trace this to the convexity of the upper part of the thorax on the right side; that is consequent on the upper curvature of the spine; the upper curvature of the spine is consequent upon the lower curvature; and the lower curvature upon the inclination of the spine upon the pelvis; and the inclination of the pelvis is (as I have explained) consequent upon the mode of standing or sitting.

Thus, gentlemen, I have laid the foundation of your understanding this subject securely on the anatomy; and not on the anatomy of the dry bones, which, for ought you know, may be artificially distorted; but here you see the texture of the whole trunk is loose and elastic, and yet the parts lie with that unnatural relation to each other which exhibits the distortion to be a consequence of a universal accommodation of all the parts—muscles, tendons, ligaments, cartilages, to the forms of the solid bones. I shall not go further into the discussion of the treatment in this kind of distortion, which is distinguished by the term lateral curvature; but I shall take an early occasion to draw your attention to those instances of *disease* of the spine of which we have many examples in the hospital.

REMOVAL OF A LARGE PORTION OF THE SCAPULA.

To the Editor of the London Medical Gazette.

SIR,

SEEING a short notice of an operation, which I performed on the scapula, in your last number, I have taken the liberty of sending you a more lengthened detail of the case, thinking that it might prove interesting to your readers. Should your opinion so far coincide with mine, I beg you will insert it in your pages.

I am, Sir, yours, &c. &c.

J. LUKE.

1, Broad Street Buildings,
Nov. 9th, 1829.

Jane M'Carthy, a healthy looking little girl, with a clear fair complexion, aged 14, was admitted, October 6th, 1828, a patient of the London Hospital, for a tumor which occupied the lower part of the dorsum of the left scapula, a little above its inferior angle. It was at this time about the size of a small orange, adherent, and growing from the surface of the bone, and following all its motions. It was well defined, yet softish and elastic; painful, yet not inflamed or discoloured on the surface of the skin. She complained of nothing but the tumor. She had no difficulty of breathing, nor cough; her bowels acted regularly, and she had no pain in the abdomen, nor headache. She attributed the origin of the tumor to carrying a child on the arm of the same side, which she conceived had strained the shoulder. It was only five weeks since she first observed the tumor, but she had experienced much pain in the part for more than five months preceding. Since she first discovered the tumor, it has increased in size up to the time of admission; attended with heat of the surface.

The case was considered one of medullary sarcoma, becoming developed with extraordinary rapidity. Ordered *v. grs.* of Plummer's pill to be taken every night; 10 leeches to be applied to the tumor every other day; the goulard lotion to be used continually; milk diet; and, lastly, to be kept perfectly quiet in bed.

October 9th.—The tumor has much increased in size, and is evidently fast approaching the spine of the scapula. It has also become much more painful, and the skin more tense and hot. The motions of the arm produce much uneasiness, while an aching sensation continues permanently at the seat of disease. Another tumor has also sprung from underneath the scapula, extending from the anterior costa towards the axilla. It is not of any considerable size, but seems to be connected with the venter opposite to the tumor on the dorsum, and follows all the motions of the bone. Ordered the pill, lotion, and leeches to be continued.

10th.—The tumor still increases rapidly, both on the dorsum and venter. That on the dorsum advances towards the spine of the scapula; that on the venter towards the axilla, under the *latissimus dorsi*. The pain and tension have also increased. Ordered to continue as yesterday.

14th.—To-day, at 1 o'clock, she was conducted into the consulting room, for the purpose of obtaining the opinion of the other surgeons of the hospital. The tumor had considerably increased in size, and had become more painful, and the skin tense. It now occupied nearly the whole of the infra-spinal fossa, with the exception of a small portion near the cervix, and had become more prominent. The tumor, from the venter, had extended deeply into the axilla. The dorsal tumor, when pressed with the finger, felt elastic and fluctuating, as if containing a fluid. This feel, together with the rapid development of the tumor, seemed to give some colour to the opinion that the disease was abscess. Yet the feel towards the axilla militated against such an opinion, for this was solid, and the scapula moved easily upon the chest. It was, however, thought advisable to determine this point fully before any ulterior steps were proposed, by puncturing the tumor with the lancet. This I accordingly did, and gave exit to a quantity of blood, mixed with a brainlike substance. On introducing my finger into the opening, I found that it passed into a soft pulpy mass; and thus, whatever doubts might before have existed as to the nature of the disease, were now removed: it was decidedly medullary sarcoma. The next point for consideration was the ulterior step to be taken. We had before us a disease intractable in itself, and uniformly producing fatal consequences if not removed by operation; and the operation itself very frequently, if not most frequently, unsuccessful, from the disease returning either in the cicatrix or in some distant part. The disease, too, was making such rapid progress that a very short time would put all debate about the propriety of an operation out of the question. It had already advanced to such an extent as to require the removal of a very considerable portion of the scapula, and the laying open of nearly the whole axilla, for its perfect insulation from the surrounding structures. Every thing required that an operation, if determined on, should be done promptly, to render it likely to save the patient. There were many difficulties, too, which seemed to militate against its performance; such as its magnitude, the fear of hæmorrhage, the difficulty of insulating the disease; the danger, the uncertainty as to the use which would be enjoyed in the member

after the recovery ; to which I may also add, the want of precedent for the removal of so large a portion of scapula under similar circumstances. It was determined that, notwithstanding these difficulties, it would be advisable to make an attempt at least to save our patient by removing the tumor, and so much of the scapula as should be required for its separation.

For this purpose my patient was placed upon a table, on her right side, with her face inclined a little downwards. The arm was raised by an assistant from the side, so as to expose the axilla ; while the clavicle was depressed as much as possible upon the first rib, in order to admit of compression of the subclavian artery, which was directed to be done by means of a pad.

Having placed myself behind my patient, I made an incision through the skin, beginning at the axilla, and extending it along the axillary margin of the tumor and anterior costa, and then with a sweep around the inferior angle to within a short distance of the spine of the scapula. I extended a second incision from the commencement to the termination of the first, along the lower margin of the spine ; also through the skin, which being drawn upwards, exposed the spine and adjoining muscles. The muscles lying over the supra and infra-spinal fossæ were next divided in the direction which I proposed to saw through the bone. Thus the back part of the deltoid, and corresponding portion of the trapezius, the teres minor, infra-spinatus, and supra-spinatus, were cut through down to the scapula. By grasping the tumor and inferior angle in my left hand, the scapula was steadied while I sawed it through, in a direction extending from a little behind the glenoid cavity to a little above the superior angle, which latter, therefore, was removed. To effect this the spine was sawn through near to the root of the acromion ; after which the levator scapulæ, sub-scapularis, the insertion of the trapezius to the root of the spine, and the rhomboidei, were divided ; and the base of the scapula dissected off from the ribs towards the axilla. The tumor was next to be dissected from the axilla ; for which purpose it was grasped in the left hand, and drawn out, while I cut close upon my fingers with the other. I was under the necessity of laying bare the axillary nerves and artery ; the lat-

ter of which could be seen pulsating down the arm ; so close did the tumor reach to these parts. The vessels divided at this part of the operation poured out blood pretty profusely, but were soon compressed by prompt assistants. The teres major, part of the latissimus dorsi, and serratus, were subsequently divided, and the tumor detached, leaving a very large surface of wound exposed, and the extremity perfectly loosened from the trunk. There were twenty or thirty vessels requiring ligature ; some of which, in the axilla, were of considerable size, and close to the trunk of the axillary artery itself. There was not, however, much difficulty experienced, nor was there more than a pint, or a pint and a half of blood lost. She bore the operation remarkably well, and did not faint. When the vessels were attended to, the wound was brought together by straps of adhesive plaister, leaving a very little interval between its sides, considering the magnitude of the surface exposed. The arm was secured to the side by a bandage carried around the chest, and the fore-arm placed in a sling ; by which means the requisite degree of fixity was given to the whole member.

After being placed in bed, she complained of considerable pain in the part, but did not appear much reduced by the operation. Ordered xxx. drops of laudanum, to be taken immediately. In half an hour, the pain continuing undiminished, xx. drops more were given, with the effect of procuring ease ; after which she continued free from pain for the remainder of the day, and slept a little.

The tumor, on examination, presented the ordinary appearances of medullary sarcoma arising from bone. It was composed of a brain-like substance, with spiculæ of bone extending into it from the surface of the scapula. The consistence of the dorsal and ventral tumors differed in the first being more pulpy than the last. Their limits were defined, and their circumference vascular. Their size was sufficient on the one hand to fill nearly the whole infra-spinal fossæ ; on the other to extend from the venter, opposite to the first, deeply into the axilla. The surface of the scapula, although rough from projecting spiculæ, did not appear to have been absorbed ; hence the bone formed a septum between the two tumors. The tumor had been completely insulated,

and was invested by the scapular muscles. About three-fourths of the scapula had been removed, embracing the whole but the glenoid cavity, neck, acromion, and a small portion only of the spine and fossæ; and the following muscles divided — deltoid, trapezius, levator scapulæ, rhomboideus major and minor; supra-spinatus, infra-spinatus, teres-minor, teres-major, latissimus dorsi, serratus magnus, and sub-scapularis.

15th, 8 A.M. — Has slept nearly through the whole night, and continues free from pain. There is but little acceleration of the pulse. The skin is scarcely more hot than ordinary; and there is not much thirst, but she feels a little sick. Ordered saline effervescing mixture, with 3ij. of Epsom salts, every two hours.

7, P.M. — Has slept much during the day, and has no pain. She breathes freely, but rather quick. Pulse 140; skin hot and dry; tongue furred, attended with thirst, but is moist upon the surface. Bowels have not been relieved; the sickness has gone off since she took the first dose of the mixture. She is rather restless, and complains of her position in bed, and also of the hardness of the straw of which the bed is made. A feather-bed was substituted, and her position changed by raising her head with pillows. Ordered to continue the mixture until the bowels are relieved.

16th, 8 A.M. — Has passed a comfortable night, having slept some hours. Pulse 130; skin hot and dry; tongue furred on the edge, with a dry brown streak in the centre. Complains of thirst, and has little or no appetite. Bowels have been relieved once by the medicine. Ordered to continue.

1 P.M. — The bowels have been relieved copiously two or three times, and she feels better. There has been much discharge from the wound, which has soiled the bed and bandages, and smells offensively. The outer dressings were therefore removed, and the discharge cleansed away. There was little or no tumefaction; and the sides of the upper part of the wound were discovered, through the intervals of the remaining plaister, to have adhered. Fresh outer dressings were applied, and the arm secured as in the first instance. During the operation of dressing she fainted.

8 P.M. — Complains of pain in left breast, over the pectoral muscles, which is increased when she makes a deep inspiration. There is a slight swelling, apparently produced by an unusual contraction of the muscle, as the shoulder is drawn preternaturally forward. She is in every other respect easy, and disposed to sleep. Pulse 136; skin warm, and rather moist. Tongue more moist, but still furred and brown in the centre. She is evidently weak, and slides down in bed. Ordered to continue the mixture every four hours; 1 gr. of calomel, with $\frac{1}{2}$ gr. of opium late at night; and to apply x. leeches to the swelling on the pectoral muscles.

17th. — Pain in the tumor has subsided; the pulse is less frequent; the skin more moist; the tongue more moist; and loosing its brown streak. The bowels have been relieved, and although weak, she appears to be much improved. Ordered to omit the mixture; to repeat the pills at night; and to take some beef-tea.

18th. — The wound again dressed, and going on well. There is a clean granulating surface at its lower part, while the sides of the upper have coalesced. General health improving; strength increased; and appetite better.

Nov. 10th. — The wound has been dressed daily, and is healing. She has now acquired sufficient strength to sit up a little, and every thing is going on favorably.

Jan. 2d. — To-day she is sufficiently well to leave the hospital, having improved unremittingly up to this time. There is still a very small surface of wound unhealed, not larger than a small bean. She has not yet been permitted to use her arm, to ascertain what power or motion she possesses.

20th. — The wound healed within a few days of her leaving the hospital, and the cicatrix is now firmly closed. We thought proper to make some few trials of the strength which the arm possessed, and the degree of motion which she enjoyed. She stated that she experienced a sense of weakness of the whole limb, which prevented her from lifting more than light substances, such as her work while sewing. All attempts at lifting heavy articles were attended with pain of the shoulder, which compelled her to desist. Thus, when requested to lift from a chair a moderate sized octavo bible, she was unable to raise it

more than a few inches, and again laid it down, from pain and fatigue. She possesses the free motion of the forearm and hand, and can move the arm forward, but not upward or backward, nor can she rotate the arm in either direction. She is in good health: she was requested to use the arm as much as she could conveniently to herself.

Sept. 20th, 1829.—My patient again paid me a visit at the hospital, since which I have had many opportunities of witnessing the extent of power and motion which she has gained since her visit in January. I was now much gratified in observing how nature had accommodated the parts to the new state of things; for although the motions of the limb were not so perfect as before the performance of the operation, yet she enjoyed much more than could have been reasonably anticipated. She possessed motion sufficient to enable her to perform with ease all her ordinary household duties. The motions forward and backward were perfect, and in fact more than ordinary, the limb moving with more than usual pliancy, but yet there was considerable power. She can also perform the actions of rotation outwards and inwards. The elevation of the arm from the side cannot be easily accomplished, and requires the aid of the opposite hand to raise it to a horizontal level. She possesses considerable power, and can lift with ease moderately heavy substances. Thus, she can nurse an infant on the arm almost with the same ease as before the operation. If, however, the weight be greater than she can conveniently carry, she immediately experiences a pain in what may now be called the superior angle of the scapula, which is rendered prominent, and the skin over it tense. The muscles of the arm are not shrunk, with the exception of the deltoid, which sinks under the projecting acromion. The cicatrix has become much enlarged since the healing of the wound; it seems perfectly healthy and firm, but when pressed upon appears tender. The trapezius and rhomboid muscles are so united to the cicatrix and skin that she possesses the power of moving both at will, independently of any other part. She is in perfect health, with the exception of an occasional headache, and has had no return of the disease during the twelve months which have elapsed since the removal of the tumor.

LITHOTRITY.

To the Editor of the London Medical Gazette.

SIR,

HAVING witnessed with great satisfaction the demonstration of M. Civiale's instruments for performing the operation of lithotry, made by Mr. Costello, before the Westminster Medical Society last Saturday evening, it occurred to me that a few practical remarks upon the results likely to ensue from this important discovery would not be unacceptable to the readers of your Journal, the more especially as the discussion which took place at the society above alluded to was too restricted in point of time to allow a fair *summing* up of the question at issue, between the operations of lithotry and lithotomy. Nevertheless, I am not vain enough to suppose that, in the few remarks which I now have to offer upon this subject, I shall satisfy every objection, or make what is so clear and apparent to my own mind, equally convincing and satisfactory to others. But I will waste no farther time in prefatory remarks.

Those who witnessed the display of the mechanism of the instruments shewn by Mr. Costello, and the power they evinced in seizing, crushing, and breaking down the calculi which were operated upon, must be convinced, I think, that the instrument possesses in reality the necessary facilities for effecting the purposes in view. Its complexity is not greater, certainly not more than is perfectly consistent with its safe and effectual management in the hands of any person who will take the trouble to give his attention, for a very limited time even, to the principles of its construction; nor must it be considered as an objection that it *does imply* considerable dexterity and manual tact in its application; and what great operation in surgery does not require the same qualifications? Nor must it be forgotten that this operation is not one that starts up at once, assuming a perfect shape; that it has arrived at its present state of comparative perfection (perhaps still capable of much improvement) only by slow and progressive steps; that it is not the result of fortuitous circumstances, but is a truly scientific application of the principles of mechanics, for a purpose and in a situation to which no insuperable objections can be raised either by

the anatomist or physiologist. That there are difficulties attending this operation, no one can doubt; and I, among others, was much impressed with the very candid manner in which Mr. Costello stated those difficulties; and this brings me at once to consider the objections raised against the operation of lithotritry. These are of two kinds; one set of objectors confining themselves to the difficulties and embarrassments likely to ensue in performing the operation, the other party advocating the perfection, facility, and safety of the present mode of extracting calculi by the lateral operation. I will begin with the last class of objectors; and I will ask whether it be really true that the lateral operation of lithotomy be, as was asserted, simple, easy, and safe. Abstractedly considered, it may be a matter of surprise that so much importance should be attached to making a clean cut through skin, cellular membrane, and a few muscular fibres, into a cavity not very sensible in itself, nor much addicted to inflammatory action of an acute kind; but every surgeon will nevertheless allow, if he be not afraid to avow the truth, that he approaches this operation with trembling and apprehension, and that arising from results which perhaps cannot be argued upon, but which are every where felt. It is true that, in some hands, the lateral operation of lithotomy has been eminently successful; but that success has usually been confined to certain situations or seasons, or has ceased altogether with the life of some particular person. Those who are conversant with the history of surgery, need scarcely be reminded of particular examples; but to shew the universal feeling as to the dangerous nature of this operation, let us only observe the armoury of different instruments that have been proposed for effecting this one end: knives of all kinds, gorgets, some at a particular angle, the *bistouri cachée*, strait staffs, &c.: all demonstrate, as plainly as any language can speak, the apprehensions that have suggested these various alterations or changes. Add again, whence arises, if not from the same source, the different modes which have been at various times suggested of making the opening into the bladder? Hence has arisen the high operation, the lateral operation, that called the recto-vesical, besides many little variations in the lateral operation made by almost every

one who has undertaken its performance. Now with regard to the ratio of mortality following this operation, I am almost afraid to speak; but I *know* it to be greater in proportion, not only than that of any other operation in surgery, but I believe I might say of any two of the most capital operations put together. This mortality proceeds sometimes from obvious causes, but at others it occurs contrary to all expectation; is even not to be understood upon inspection of the body after death, and has therefore been referred to the shock which the system receives at the time. Of the obvious causes we have hæmorrhage, enlarged prostate, diseased bladder, diseased kidney, peritoneal inflammation, and often inflammation and sloughing of the cellular membrane connecting the bladder to the neighbouring parts. This is a formidable, but it is a true list of casualties, and its accuracy will, I am convinced, not be denied by those who have either performed lithotomy or witnessed the result of its performance on the large scale. Now any operation which can be substituted for one so replete with accidents and so pregnant with danger, which, at the same time, offers as certain means of getting rid of the calculus at a less risk of life, cannot but be hailed as a vast improvement in the art of surgery; and this brings me to consider the objections raised to the operation of lithotritry. No one will deny that enlarged prostate gland, diseased bladder, affections of the kidney, old age, and broken health, are all formidable drawbacks to the success of the lateral operation of lithotomy; they are also objections to lithotritry, but they are not *greater objections*—they do not *forbid* its performance—which, in the other instance, they frequently do: they would only dictate to the operator a greater degree of caution, and induce him not to continue the action of the instrument for too great a period of time at one sitting. The only *real obstacle* to the performance of lithotritry, is the presence of stricture in the urethra; and it is obvious that this objection also applies to the lateral operation, for a staff must be passed into the bladder by the urethra even in that case; and therefore, though the objection applies certainly with more force in the operation of lithotritry, it is still an objection to the lateral operation. It has been said that the lithotrite may grasp a fold of the bladder;

that in some cases (a flat stone, for example) the difficulty of seizing the stone may be very great; that should the calculus be sacculated, it cannot be laid hold of at all; that the instrument may break in the bladder; and, finally, that a fragment or more may be left; thus laying the foundation for a second calculus. I pass by the objection to the mode of sounding by an instrument of a greater curve than usual, because practical men must be aware that this is not a difficulty inherent solely in this mode of exploring the bladder, which is in no case infallible; but that, as the bladder is distended previously with water in the operation I speak of, this difficulty is thereby, in some measure, diminished. First, as to the chances of grasping a fold of the bladder, it must be recollected that the bladder is filled with fluid, and therefore the probability of such an accident is greatly lessened; but as it has once confessedly occurred, it must be admitted likely to happen again, though the improvement in the construction of the instrument renders this not so likely as it formerly was. Now, considering that the *touch* of a stone, however small, may be easily recognized; that the three branches of the instrument are of unequal length, and that the index would mark the extent of their *closure*, it is not probable that this accident should occur in the hands of a skilful and careful operator; but if it does, would not the sensation of a soft substance included within the instrument, which must necessarily be nearly closed, be detected by the surgeon?—and is there any thing to prevent him, then, from opening the instrument, so as to let go the substance he had grasped, and then to withdraw it a little towards the centre of the bladder? Secondly, if the stone is flat, it may be difficult to seize. This is admitted; but as it is only a difficulty, and not an objection, it may be got rid of by renewed trials, and that manual dexterity which practice gives. Thirdly, should the stone be sacculated, it cannot be got at by this instrument. This is true, and would undoubtedly prevent its use in such a case; but this circumstance is a very rare one, and may be admitted to be an objection in every mode of operating. Fourthly, the instrument may break in the bladder. This objection will scarcely be made by any one who has attentively examined the ma-

terials and strength of the instrument; it may be fairly said, therefore, that this charge is chimerical and groundless. Fifthly, a fragment of the calculus may be left in the bladder. True; but as the instrument can crush and break these fragments to the minute division of one or two lines in diameter, it can scarcely be supposed that such fragments will not be enabled to pass through the canal of an urethra which has been previously stretched by the use of bougies; and this brings me to observe, that though many persons have imagined that obstacles might exist to the passage of a straight instrument into the bladder, yet, as this is a matter to be settled merely by practice, and which reasoning alone can never decide, I may confidently appeal to that practice, as proving that, in this respect at least, no difficulty does exist. Again, it has been urged that a very hard calculus might resist the action of the lithotrite; but those who have seen its powerful operation will admit at once the unreasonableness of such a supposition. I have thus hastily and cursorily passed in review the principal objections brought against lithotritry; I have contrasted its probable results with those of the lateral operation for lithotomy; and I come to the conclusion that the former operation is applicable to every case in which the latter has been employed, and that, in difficult cases, it affords the patient a more rational chance of safety. It can only be by an appeal to facts, and a statement of numbers, that the superiority of this new mode of getting rid of so dreadful a disease as stone in the bladder can be confirmed; and to that statement I feel confident the supporters of lithotritry may fearlessly appeal. This operation has been performed many hundred times on the continent; it is now getting into notoriety in this country, and it will be no very difficult matter to shew that a great proportion of those who have been so operated upon have been permanently relieved, whilst their sufferings and danger have been greatly diminished, and the instances of failure, or fatal result, have been comparatively rare. I have to make many apologies for the defects of this sketch, which has been written in haste and on the spur of the moment.

J. BACOT.

Portugal Street, Nov. 16th.

ON THE
MEANS OF AFFORDING
RESPIRATION TO CHILDREN IN
REVERSED PRESENTATIONS.

By JACOB BIGELOW, M.D.

Professor of Materia Medica in Harvard University.

It is familiar to obstetric practitioners, and is noticed by most writers on midwifery, that in those cases of labour in which the body is delivered before the head, a considerable degree of danger exists in regard to the life of the child. Rules for the conduct of such cases are laid-down by writers, yet it cannot be denied that, in the hands even of skillful practitioners, many children which are alive when the body is expelled, are irrecoverably lost before the head can be extracted. In these cases death takes place because the connexion with the mother is interrupted, by compression of the cord, or detachment of the placenta, before a communication with the atmosphere is effected.

It is the object of the present paper to show, that in many such cases the life of the child may be saved, by forming a communication between the mouth and the atmosphere, previous to the delivery of the head.

After the body is expelled, if the head can be seasonably delivered, either by the recurrence of pains, or by the successful efforts of the practitioner, no difficulty ordinarily occurs. But this desirable state of things cannot always be realized: too frequently the size of the head, and the resistance of the pelvis or soft parts, renders the delivery difficult and hazardous, and the practitioner, in the midst of his efforts, is apprised, by a convulsive jerk or spring of the body, that a state of extreme danger exists, and that the time has come at which the child must breathe, or will speedily die. If at this period the fingers be introduced, so as to reach the mouth of the child, it will be perceived that each jerk of the body is attended with a gasp, and convulsive effort at inspiration, performed by the mouth and chest of the child. In this state of things, if air be conveyed to the mouth of the child, it will immediately breathe, and the efforts of nature, as will hereafter be shown, may in

most cases be safely waited for to assist in expelling the head.

The method to be pursued in conveying air to the mouth, depends upon the situation of the head. If the chin has descended low in the pelvis, so that the mouth rests upon the perinæum or lower part of the sacrum, and can be readily reached by the fingers, the hand of the operator alone is sufficient to give the assistance required; but if the mouth is situated so high in the pelvis as to be reached with difficulty, or if, from the large relative size of the head, there is much compression, the assistance of a tube may be of use. The mode of proceeding which I have found successful in various instances is as follows:—As soon as the body and arms are extracted, supposing the face towards the sacrum, an assistant supports the body, carrying it towards the pubis; or the reverse, should the position of the face be to the pubis. The accoucheur should then introduce the hand to which the face looks, till the middle fingers rest upon the mouth of the child; the hand is then to be raised from the throat of the child, making the ends of the fingers a fulcrum, and pushing the perinæum backwards: the air will thus pass upwards as far as the chin of the child. The middle fingers are now to be separated, about half an inch from each other, and thus a complete passage will be formed between them, by which the air will reach the mouth of the child. If the child be in a healthy state up to this period, it will immediately breathe and cry, and the delivery of the head may be safely postponed until the natural pains recur. If, from any degree of asphyxia, the child does not immediately breathe, it may often be made to do so by dashing cold water upon the body, or by other stimulating processes. It has even appeared to me practicable to inflate the lungs, in some cases, through an elastic catheter. When the mouth is so high in the pelvis as to be reached with difficulty, or when the compression is so great as to obliterate the cavity between the fingers, a flat tube will be found useful, made of metal, of spiral wire covered with leather, or of elastic gum, and having its largest diameter about half an inch. If the tube be of metal, or of any incompressible material, it should be withdrawn during a pain, to prevent contusion of the soft parts, and immediately

replaced, if the pain subsides without expelling the head. Such a tube may be considered as a prolongation of the trachea, and is fully sufficient to sustain life by respiration for a considerable time. The tube must be guarded and directed by keeping it between the fingers of the inserted hand.

The following are a part of the cases which have occurred to me in practice, affording an opportunity for the trial of this method:—

CASE I.—A patient was in labour with her second child, August 8th, 1824. The case was one of breech presentation, and without any unusual occurrence the body and arms were delivered in about three hours after my arrival. The position of the head was of the most common kind, with the vertex above the pubis, and the face in the lower part of the hollow of the sacrum. At this time my left hand was passed upward, with a view of depressing the chin, but the child being large, it required some effort to reach the mouth with the fingers. The time consumed in doing this was too great for the safety of the child, and the convulsive spring of the body took place. I was forcibly struck at the same moment by perceiving a gasp of the mouth at the ends of my fingers, and the idea occurred that if a communication could be made to the atmosphere, the child would respire. Attempts were made without success to extract the head by a moderate force, aided by the efforts of the mother and by pressure made by an assistant over the fundus of the womb. At the same time the hand which rested over the mouth and throat was raised a little, and the fingers opened to give passage to the air. The child soon gave another convulsive spring, and at the same moment inspired. The hand being retained in the same position, a slow, but constant respiration continued, accompanied with a low, moaning cry, for eight or ten minutes, when the recurrence of a pain caused the head to be delivered. During the whole of this period, before the final pain, the mouth was several inches within the perinæum.

CASE II.—This case occurred May 1st, 1826, and was also a breech case. Being a first labour, it was protracted for 18 hours. After the presentation was ascertained, I had made, in a hasty manner, a tube about five inches long, and half an inch wide, slightly flattened,

and slightly bent over at its extremity. The case being one of more than common interest, I provided myself likewise with forceps. Although the mother had been in perfect health, yet the body of the child, when expelled, was found emaciated and dark coloured, exhibiting marks of feeble life. As much force as it was thought justifiable to use was employed to extract the head, with no other effect than to bring the mouth within about two inches of the edge of the perinæum. The tube was now introduced, and placed in the mouth of the child, but it did not respire. It will be observed, that the child had exhibited no convulsive effort, nor any signs of being alive. An attempt was now made to inflate the lungs, which failed, apparently from want of tightness in the tube, the joining not having been soldered. It nevertheless appeared to me practicable to have inflated the lungs in this situation, with a suitable tube, since the tightness with which the perinæum covers the face would assist in preventing regurgitation of the air. The foregoing attempts having proved unavailing, the forceps were introduced, with the aid of which the head was extracted. The child was resuscitated with great difficulty, and did not breathe spontaneously, until artificial respiration had been kept up, by inflating the lungs through a quill, for more than half an hour. It was two hours before the respiration became so perfect that the child could be left to itself. I have no doubt that this child would have respired before the birth of the head, had there been sufficient constitutional vigour to produce the effort.

CASE III.—March 29th, 1827.—This patient had had five children. In her sixth labour the presenting part was found to be the arm. The pelvis being large, and the parts dilatable, no difficulty occurred at the proper time in introducing the hand, rupturing the membranes, and finding the feet, which were brought down, and the body delivered. The face turned towards the perinæum, the mouth was easily reached, and the fingers were opened to give passage to the air, as before described. No struggle nor attempt at inspiration, however, occurred. A handful of cold water was then dashed upon the body, upon which the child immediately gave a spring and began to cry. The head was not delivered until some minutes afterwards.

CASE IV.—In a case of twins, Jan. 29, 1829, the first child presented the nates, and was born with the face to the sacrum. After the delivery of the body, the fingers were passed up to the mouth of the child, and opened, to give passage to the air. As in former cases, the child began to cry in a low voice, with slow respiration, the mouth being two or three inches within the perinæum. Feeling secure in regard to the life of the child, I determined in this instance to use no extractive effort, but to wait for the expulsive action of the uterus. In the meantime I called the attention of the females who were present to the crying of the child, which continued without interruption, though the head and neck were buried in the pelvis. In a few minutes an expulsive pain threw out the head with very little assistance on my part. The presentation of the second twin was natural.

CASE V.—This occurred in the same patient as Case III. In this labour, the presenting parts were the breech and left hand. After the birth of the body, the face was found so strongly pressed against the sacrum, as to render it difficult to form a passage for the air. By a gentle extractive force, the head was made to descend lower in the pelvis, and a tube was placed in the mouth. The child in this situation respired, and, after a few minutes, with the assistance of a pain, the head was easily extracted.

The foregoing practice is not new, though it appears to have been lost sight of by most of the later writers on midwifery. I am not aware that it is mentioned by Smellie, Denman, Hamilton, Burns, or Dewees. Merriman alludes to it as a thing which is possible, but does not speak experimentally on the subject. In one of the older writers, however, a practice nearly similar is described, and warmly recommended from the author's experience. In Pugh's *Treatise of Midwifery*, published in 1754, are the following instructions:—

“The arms being brought down, the head only remains to be extracted, which must be done with as much expedition as possible, as indeed the arms ought to be; for when the child has passed the navel, the circulation between it and the mother is stopped, from the pressure of the umbilical rope. You must then introduce the fingers of your left hand into the vagina,

under the child's breast, and put the first and second fingers into the child's mouth pretty far, so far, however, that you are able to press down the child's tongue in such a manner that, by keeping your hand hollow, and pressing it upon the mother's rectum, the air may have access to the larynx; you will soon perceive the thorax expand, as the air gets into the lungs. Many authors make very little trouble in extracting the head; but without a well-formed pelvis, every operator must know there is difficulty, and great danger of losing the child by its stay in the passage; but by this method of giving the child air, I have saved great numbers of children's lives, which otherwise must have died.

“Before I made use of this method, and pressing externally to assist in extracting the head, I found many children were lost in this situation for want of air, which put me upon inventions; as likewise a third, which was a curved flattish pipe; as likewise a flexible one, that I introduced into the child's mouth as near to the larynx as I could, the other end external, which I found answer; but now, as I find my fingers generally answer, I seldom make use of it*.”

ANALYSES OF BRITISH MEDICAL JOURNALS.

EDINBURGH MEDICAL AND SURGICAL JOURNAL.

October 1829.

[Concluded from last number.]

Case of Poisoning by Arsenic, with observations; and of Fracture of the Ribs, with Rupture of the Pleura Costalis, in progress towards a cure. By EBENEZER GAIRDNER, M.D. Fellow of the Royal College of Physicians, &c.

In this case the patient died within fourteen hours of the time he had swallowed the poison. The only circumstance worthy of remark as to the symptoms, is, that he had cramps of most of the voluntary muscles—that they were found to retain their rigidity

* American Journal of the Medical Sciences.

After death—and that the heart was contracted and firm, “like cartilage.” The quantity of the poison swallowed is supposed to have been about half an ounce.

A Sequel to Reports on the Diseases of Plymouth. By EDWARD BLACKMORE, M.D. Physician to the Plymouth Public Dispensary, &c.

This is one of a series of papers, containing much valuable information on the subject of medical statistics; but of which, from the numerous tables, and multifarious points embraced in it, no just idea can be given within our limits.

On a new Mode of employing the Nitrate of Silver as a test for Arsenic. By PATRICK FORBES, D.D. Professor of Chemistry, King's College, Aberdeen.

Dr. Forbes, after detailing some objections to the ordinary method of proceeding in the attempt to detect the presence of arsenic, thus explains his own plan—

“The following mode of procedure avoids all the sources of ambiguity arising from the presence of muriatic acid or any of its combinations, or of the alkaline phosphates; and it is so simple, that any person, at all capable of performing chemical experiments, may conduct it in a satisfactory manner.

“1. The suspected liquid must be carefully filtered, and if very viscid, may be diluted with *warm* distilled water. If after filtration it has colour, it should be diluted with distilled water till the colour has *just* disappeared. A solution of nitrate of silver (which precipitates free muriatic acid and all its combinations, decomposes all the alkaline phosphates, and precipitates the phosphoric acid in combination with the silver, but has no effect by simple affinity on arsenious acid) is then to be dropped into it till all precipitation ceases. The liquor must again be filtered, and solution of nitrate of silver added, when no precipitate will appear if sufficiency of nitrate of silver has been formerly used. If any precipitate do appear, an *excess* of nitrate of silver must be added, and the liquor again filtered. Take now a small glass rod, and dip the point of it in a solution of

pure ammonia, and just touch the surface of the liquor with it; in a few minutes, if any arsenious acid be present, abundance of the well marked yellow precipitate of arsenite of silver will diffuse itself down through the liquor.

“2. Great care must be taken to add very little of the pure ammonia. The reason is, that the pure ammonia in excess has the power of dissolving the arsenite of silver. This property of ammonia affords, therefore, a second decisive test; for, after the precipitate has been fully formed, it is only necessary to add ammonia in excess, when, if the precipitate be arsenite of silver, it will on stirring be perfectly dissolved, and the liquor will appear colourless as before.

“3. By adding nitric acid to this colourless liquid till the ammonia is neutralized, the precipitate of the arsenite of silver may be again made to appear,—which affords a third proof of the nature of the precipitate.

“4. The precipitate may now be collected, mixed with black flux (both being made quite dry), put into a glass tube, and the arsenic sublimed and condensed in its metallic state.

“It will be observed, that I have not directed the contents of the stomach to be boiled before the test is applied. The reason of this is, that it is wished to prevent the union of the arsenious acid with any free alkali which may happen to be accidentally present, which would prevent the success of this process. The application of *warm* distilled water on the contents of the stomach in the filter will, however, be found sufficient to carry along with it all the arsenious acid, and will not in any way interfere with the future steps of the analysis.

“The use of nitrate of silver employed in the above manner in the detection of arsenious acid recommends itself by its simplicity, and by the ease with which the substances employed may at all times be procured. But it by no means supersedes the employment of sulphuretted hydrogen, which also affords excellent indications of the presence of this poison. Every liquor supposed to contain arsenious acid should be subjected to both these re-agents; and if both these tests exhibit the appearances which ought to follow their use if arsenic be present, there cannot remain the smallest doubt on the mind of the

analyst, and he will be enabled to give his testimony with the most unhesitating confidence.

"If any one wishes to satisfy himself of the accuracy of the method now detailed, he has only to make a mixture of any muriates, alkaline phosphates, solution of arsenious acid, decoction of onions, coffee, &c. and to proceed as above directed.

"It deserves attention that the precipitate must be guarded from the *direct rays* of the sun, which will immediately turn it black from the presence of nitrate of silver and vegetable matter."

On the Use of Quinine in the Ague of Dublin, and its power in accelerating Mercurial action. By WM. HARTY, M.D. Member of the King's and Queen's College, &c. &c.

Dr. Harty has been led to believe that ptyalism is much more easily induced when mercury is combined with sulphate of quina, than when exhibited alone; nay, he is of opinion that in some cases the mercurial action, after it has subsided, may be reproduced by giving the quina alone, and without any repetition of the mercury.

Case of Intestinal Obstruction successfully treated by Mechanical Means. By ALEXANDER RUSSEL DUGUID, M.D. Kirkwall.

Dr. Duguid was called to a patient labouring under intestinal obstruction, in a part of the country at a distance from any place where medicines could be obtained; and some doses of castor oil, croton oil, &c. having been exhausted, he was obliged to trust to mechanical means for the relief of his patient: he thus describes his proceedings:—

"Dilatation of the rectum with warm water, thrown up by Weiss's powerful syringe, was next resorted to. As soon as about a pint and a half were thrown up, he complained of much pain and distention, and it was returned with great force in spite of my efforts to prevent it, and without any trace of feculent matter. This was frequently repeated with the same result. I then introduced the elastic tube of Weiss's instrument, well oiled, about ten inches into the rectum, and finding an

obstruction to its further passage, I fitted the syringe to its extremity, and continued to exhaust the air for a minute or two; but this having no effect, I attempted to push the tube past the obstruction. After some difficulty, and repeated trials, I gained a few inches, when all at once, to my great satisfaction, the resistance was overcome, and a copious discharge of very fetid flatus, with some liquid feces, took place through the tube, with almost instant relief of the distention and pain of the belly. I then fitted the syringe to the extremity of the tube, and pumped out a large quantity of feculent matter, of the appearance and consistence of yeast. When this was too solid to pass through the tube and syringe, so as to choke the instrument, a quantity of warm water was thrown in, and the pumping process resumed. In this way a great accumulation of feces was brought away, with total relief of all the symptoms. Upon withdrawing the tube, the cause of the obstruction, which indeed I had previously surmised, became very apparent, by the thin streaks of hardened feces with which the tube was coated on various parts of its surface, and which were confined to that portion of it which had passed the region, about ten inches from the anus, where the great difficulty of introduction had been experienced. An opiate enema was now administered, and I left my patient at eight A.M. of the 11th. A purgative mixture of senna and salts was sent him, which operated well, and left him convalescent."

On a New Mode of applying Galvanism without giving a Shock. By K. T. KEMP, Esq.

"Let us suppose a patient about to be subjected to galvanism by means of a common galvanic battery; that he is to receive it through the arms, across the chest; and that the circuit is to be formed by two brass balls, to one of which is attached a single wire, and to the other two distinct and separate wires. The trough being charged, the person takes hold of one of the balls, say that which has the single wire attached to it. The extremity of this wire is to be placed into the first cell of the trough, where to remain. The patient is then, with the other hand, to lay

hold of the other ball having the two distinct and separate wires attached to it, one of which wires the operator places into the second cell of the trough, while he retains the other in his other hand. The patient has now been subjected to the influence of two plates; but the intensity of the galvanism from two plates is so very weak, that not the least sensation is produced upon him. The operator now inserts the last mentioned wire, which he retained in his hand, into the third cell, he then lifts the wire which is in the second cell, and places it into the fourth, and so on, lifting each of the two wires which are attached to the one ball, alternately, taking care that one of them always forms the circuit while the other is moved forward.

"In this manner, at each removal of the wires, the quantity of galvanism added to that which is already circulating is so small, that no shock is perceived; while the general effect is distinctly experienced on the system as the wires are moved forward. Instead of adding one plate only at each removal of the wire, two, four, or six, may be added, as no distinct shock is perceived from that number; and in this manner we sooner accumulate the necessary intensity. When the patient has been subjected to a sufficient intensity of galvanism, the wires are to be removed backwards in the same manner, to prevent a shock being received.

"The effects of this modification of galvanism on the system are very peculiar. As the wires are gradually moved forwards, a slight sensation of heat and a kind of prickling is perceived in the hands and wrists, accompanied with a general glow of heat in the region through which the galvanism passes. As the number of plates is increased, a powerful tension of the muscles and accelerated circulation ensue.

"The beneficial effects of galvanism appear to depend entirely upon the passage of the fluid through the system, whereby an increased action of the different organs is induced, and the various secretions promoted; and in no degree upon the shock received, which is nothing more than the entrance of the fluid into the system, or rather, the superinducement of a particular state upon it. And, without doubt, the more gradually this is effected, and the more imperceptibly the system is again brought

into its natural state, the greater will be the benefit derived."

Mr. Kemp is of opinion that this mode of applying galvanism is particularly indicated in cases of suspended animation.

Account of the effects of the accidental inhalation of the Gas of burning coal in the Wanlockhead Mines By WM. WATSON, Esq. Surgeon, Wanlockhead.

The usual effects of such a cause, viz. head-ache, giddiness, vomiting, tremor, &c. &c. resulted in this case.

Case illustrating the origin of Tubercles in Inflammation. By JAMES LOMAX BARDSLEY, M.D. Physician to the Manchester Infirmary, &c.

In the body of a man, aged 42, who had suffered much from syphilis, the following appearances were found in the chest:—

"The left lung was much condensed, owing to considerable grey tuberculous infiltration. The apex of the right lung was studded with numerous tubercles of a grey colour, and its substance was altogether impervious to air; somewhat lower down the tubercles were less fully developed, and the pulmonary tissue was more vascular; but towards the inferior part of the organ, the inflammation of the pulmonary substance was most marked, and only a few tubercles were present. The shades of difference in these degrees of vascularity were very evident to the eye; and a striking difference in the states of density of the pulmonary tissue was also discoverable to the touch. These appearances are well shown in the drawing, which was taken from the diseased portion of lung shortly after its removal from the body."

It is on these appearances that the supposed value of the case depends, which, in Dr. Bardsley's opinion, strikingly confirms the opinion "that inflammation often precedes the deposition of tuberculous matter in these organs." To us we confess that the simultaneous occurrence of tubercles and inflammation in one case, forms very insufficient grounds for the above

deduction, and particularly as the tubercular depositions were least considerable where the inflammation was most strongly marked.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."—CICERO.

EXTERNAL RELATIONS OF THE PROFESSION.

THE division of labour in the profession has been a subject of remark with many persons, but we do not know that much has been said, however much may have been thought, of a matter of at least equal interest—the division of the profits. It is certain that immense sums of money are annually extracted from the pockets of his Majesty's liege subjects by the multitude of those who offer to them the sanatory resources of the healing art; and though it would puzzle the most subtle metaphysician to determine whether the remuneration of such services comes under the head of voluntary or involuntary actions, it must be allowed that there is nothing compulsory in the matter. No; John Bull is at perfect liberty to take advice without physic, or 'doctors' stuff' without consulting any one; to eschew all tampering with nature, or to poison himself; and, if we may be permitted the expression, to "go to the devil his own way!" And yet one would conclude, from the hue and cry that has been raised of late, that this important privilege was in danger. A moment's glance, however, at the thriving condition of those contemners of etiquette, who, while angry parties are contending for rights, run away with the main substance of all these questions, will convince any one of the contrary. The fact is, that although our colleges are appointed to see that the public do not take by the hand any

one not properly introduced and authorized by them, there is a good deal of very improper flirtation with those free personages who have forgotten to take out a license. In spite of all that professors have pronounced upon the duty of adherence to legitimate institutions, the multitude are still going astray. It is not enough that the pure and retiring candidate for favour gently insinuates his accomplishments, and "bears his blushing honors thick upon him;" the mass of mankind require something practical, and we find them following after those who are willing to make all the advances. The recommendations of regular practitioners are often written in a manner too fine for the general eye. Their less scrupulous rivals emblazon their pretensions in characters so large that those who run may read! In a dilemma so perplexing, what then is to be done? We should be very sorry to recommend any thing contrary to the dignity of modest and unpretending worth; but we have witnessed a good deal of professional coquetry, and duly appreciate the mixed feelings of those who are hesitating on the brink of active life, who would approach but dare not. To these we would hint that our profession requires not only abstract study but practical application; that it is not in consequence of ignorance that unlearned men have succeeded, but from their meeting the demand of the market; that it is the business of those who ought properly to supply this demand to impress the world with the conviction that, as a class of men, they are superior to amateurs and quacks. We are persuaded, from reflecting upon the success with which so many of these apes of scientific practitioners address themselves to the wants and fears of the community, that there is something wrong in the adaptation of the profession to public uses; that there is a reserve and prudery among us which obstructs the

efficiency of the most gifted. But why are these things hid—why have their gifts a curtain before them? There is no class of persons more decidedly required to be men of the world than we are; no calling in which monkish qualities are so little in repute as in our own; and yet, with all that has been preached about the internal economy of the profession, but very little attention has been paid to its external relations with society at large. We are deficient in activity and *esprit de corps*; we do not interest ourselves about many matters where medicine has a divided claim with other arts and sciences; we allow this neutral ground to be taken up by a set of interlopers, who are neither one thing nor another; and we have our own sluggishness to blame. But *fas est ab hoste doceri*. We are nothing, if not servants of the public: the most accurate system of medical policy would fail in its ultimate end—utility, if it did not enable men to communicate their acquirements, and join to the *savoir* a certain portion of the *savoir faire*.

MR. EARLE AND THE LANCET.

THE old saying of "having caught a tartar," is excellently illustrated by the subjoined letter, which the Editor of the *Lancet* has drawn upon himself by his defiance of Mr. Earle, and daring that gentleman to vindicate his late address to the students who attend his Clinical Lectures. The straight-forward and spirited conduct of Mr. Earle on this occasion is in keeping with his general character; and the unanswerable manner in which he has exposed the falsehood and duplicity of the common traducer, is such as to place that worthy in no very enviable situation.

The facts are briefly these. Wakley had been in the habit, for a considerable period, of doing all he could to injure Mr. Earle's reputation; a purpose, to

accomplish which he had recourse to calling him ridiculous names, to malicious insinuations, and to direct and positive falsehoods. During the last few months, however, Mr. Earle has, strange to say, been treated in a manner totally different; the *sobriquet* by which he had been designated was changed for his proper name; his cases were carefully reported; his remarks faithfully recorded—nay, the pupils have been recommended to attend his lectures; and, lastly, these lectures have been published. All this, however, we are now told, was done in irony! This is not quite fair; the Editor ought not to veil the brilliancy of his wit too much, but to have some consideration for the duller humour of his readers—else he must be content to be his own audience, and laugh at his jokes himself.

One of our earliest recollections is of an old gentleman who was an inveterate punster, but, like Wakley's irony, his wit was sometimes of that peculiar kind which no one but the author comprehends: now whenever a joke missed fire, his wife invariably said, "that's a pun;" and, of course, the expected laugh was sure to follow. We advise Wakley to adopt the old lady's plan, and, instead of following up the subject three months after with an explanation, to put at once as an addendum—"This is in irony."

The circumstances above-mentioned led to an idea, among those who did not know Mr. Earle, that he had in some way sought the change; in fact, that he had done something to effect it. Here, however, the matter would probably have rested, had not he received a formal application from the acknowledged reporter to the *Lancet*, in his official capacity as such, for the notes of his lectures, backed by all those professions as to the sentiments of his employer to which we alluded in a former number.

The indirect and more distant hints

of Mr. Wakley's *attachment* had been passed unnoticed; but this was going a step too far, and Mr. Earle took the most prompt and effectual method of shewing to the world the contempt with which he spurned the adulations of his quondam reviler, by publicly expressing his sentiments, in an address to his class.

One would have thought the dilemma rather a puzzling one even for Wakley; but not at all: he has only to adopt a certain figure of speech, that he has always at command, and which often serves those who have nerve enough to use it freely. He has but boldly to deny point blank whatever it does not suit him to admit. To be sure it requires his readers to be fools, but he has often drawn so successfully on their credulity that he is not to be easily disconcerted. Grant him but a certain portion of faith, and as to the rest "'tis as easy as lying." "It is not true," says the Editor of the *Lancet*, just as confidently as if he expected to be believed. To what extent an assertion of the *Lancet*, taken *per se*, may be good for any thing in the remoter parts of the island, we know not; but it can only be upon his country readers that he can hope to impose by such monstrous absurdities.

In former times, when lances, and not *Lancets*, were wielded for men's destruction, if any one of honourable blood denied the statement of another, they held a tournament, and tilted for their honour and their lives before assembled multitudes. Now so chivalrous has our contemporary grown, that he wishes to restore this ancient custom: he offers to come to St. Bartholomew's, attended by his reporter, as his squire, "on any evening that Mr. Earle may appoint," then and there, for the instruction and edification of the pupils, to enter into mortal combat with Mr. Earle touching the insult offered to his spotless honour. If Mr. Earle does not accept this most wise proposal, it will be evident to the whole

profession, adds the valiant Editor, "that he dare not."

We never before read such a piece of fanfaronade even in the pages of the *Lancet*. A pretty scene it would be for Mr. Earle, or any respectable man, to have a common blustering bully admitted to his class-room to insult him. We have already said, and we repeat, that the person who communicated to Mr. Earle, Wakley's expression of respect, and who asked him for his notes, was Mr. M'Cristie, the reporter of the *Lancet*. Wakley will probably deny that he sent him; nay, we doubt not that he deputed him to speak to Mr. Earle instead of doing so himself, on purpose that he might deny it if the bait did not take. He contented himself with throwing out *feelers*, that he might draw back if it was requisite; and we doubt not but that those over whom he has sufficient influence will be forthwith instructed to eat up their words again—if their conscience be not "*too tender*." The whole letter of Mr. Earle we dare swear we shall be told amounts to nothing.

Are, then, the statements of Mr. M'Cristie nothing? Are the damning charges of Mr. Weekes nothing? Were the expressions of "respect" communicated through Dr. Armstrong nothing? Were those of Mr. Fay nothing? Was the total change in the manner of speaking of Mr. Earle, in the *Lancet*, nothing? Was recommending the pupils to attend his lectures, nothing? Was publishing these lectures, nothing?

Why then the world, and all that's in't is
nothing,
If this be nothing.

MR. EARLE'S ANSWER TO WAKLEY'S DEFIANCE.

*To the Editor of the London Medical
Gazette.*

SIR,

In requesting your insertion of the following letter to the Editor of the *Lancet*, I feel that an apology is due from me to my more respectable brethren for

condescending to notice the ribaldry of his publication. I beg to assure them that I have been actuated by the consideration that in addressing the Editor, I was in fact addressing his readers; and by a conviction that the abuses of the press can only be satisfactorily restrained through the medium of the press. I have sent a copy of this letter to him, and have claimed his promise to publish it.

I am, Sir,
Your most obedient servant,
HENRY EARLE.

George-Street, Nov. 16, 1829.

To the Editor of the Lancet.

George Street, Nov. 15, 1829.

SIR,

For the first time in my life I condescend to address you in reply to your slanderous observations—your bold defiance—and your barefaced denial of the statement which I was compelled to make to my clinical class. I am induced to take the present step because I do not wish to make the lecture-room an arena for disputes. I am further induced to take this step, instead of inviting you to hear my reply in that theatre before a jury of my own pupils, because I should be apprehensive that your reception might not be quite cordial; and because the attachment and regard which they have uniformly manifested towards me would ill suit them for the office of jurors. Influenced by these motives, I prefer making the public the jury to try the present question, and your own publication the medium of communication.

I shall pass over, in silent contempt, all the low abuse and silly puerile calling of names, so worthy of a scientific journal, as they are evidently the first angry effusions of an evil spirit, which has received just castigation, but not profited by it.

I shall proceed to meet the charges: and, first, that “after a week’s preparation I am unable to speak intelligibly on disease and its treatment for the space of one hour.” For the truth of this statement I appeal to my audience, whom you rightly represent as “enlightened.” My reply to it is this: it is my custom to select the cases on the Friday, during my visit, and I often do not receive the notes of the cases from the pupils until the Saturday evening when I enter the theatre. That I am not afraid of pub-

lishing my remarks, when the subject is of sufficient importance to merit the attention of the public, the pages of the Medical Gazette, and of the Medical and Physical Journal, will amply attest. Did it not, however, strike you, who profess to be the lover of openness and fair dealing, in making this attack upon me for declining to have my extempore lectures published, that you were in duty bound to notice the conduct of Mr. Lawrence, who has withdrawn his written consent to have his lectures published, because they were not fit to meet the public eye? lectures forming a systematic course, embracing the whole of surgery; lectures which he has been years in compiling; which he delivered to his class in Aldersgate Street, and for which he received an ample remuneration. I shall only offer one more observation on this part of your paper: how did it happen that you only discovered the worthlessness of my lectures at the moment when you were refused permission to publish them? But for that refusal you would still have been too happy to have culled the fruits of my experience, to sustain your falling publication.

Your observations respecting the lectures not being gratuitous, are too absurd to merit a single word in reply.

You next state, that “it was a glaring piece of irony which was inserted in the Lancet of October 5th;” in which you say, “Mr. Earle, to his credit be it spoken, &c. &c.” Was it in irony, that in a former number, in your address to the new pupils arriving in London, you particularly recommended them to attend Mr. Lawrence’s lectures on the principles of surgery, and Mr. Earle’s clinical lectures? I have to regret much that your irony was so masked as to deceive my friends and the public, and to lead some to suppose that I had for a moment “listened to the voice of the charmer;” an imputation which cost me a sensation of real pain, which I never felt from all the abuse which ever fell from your pen.

You next state, in reply to my assertion, that you persecuted me most maliciously for years, with all the aspersions which falsehood and malignity could invent, “that the readers of the Lancet require no contradiction of this falsehood.” Allow me to refresh their memories, and to take one single instance from many. Let me refer them to No. 233, for Saturday, Feb. 16th, 1828,

page 722. They will there find your comments on a case of injury of the head, reported in the same number, at page 720. The case was briefly as follows: a patient was admitted with a severe injury of the head, which was very actively treated without success. Symptoms of pressure came on; such as paralysis of the bladder and rectum; loss of sensation of one side, with convulsive action of the muscles on the same side. The sloughy state of the wound in the scalp clearly pointed out the principal seat of the injury. Under these circumstances, it was determined, in a consultation with Mr. Vincent and Mr. Stanley, to give the patient the possible chance of recovery by the application of the trephine. At the moment when the operation was determined on, Mr. Lawrence entered the ward; and, after a few moments' observation, declared he could see no other indication except that the man would certainly die. As he would not condescend to enter into any further explanation, I did not consider it incumbent upon me to abandon my own opinion, sanctioned as it was by that of Mr. Vincent and Mr. Stanley. The operation was performed, and blood was found effused beneath the dura mater. The patient improved after the operation, and made an attempt to speak. He survived the operation 36 hours. On dissection, above *four ounces of blood* were found effused upon the brain. Here, then, was a case in which it was most apparent to any person of common sense that Mr. Lawrence had given a hasty and most erroneous opinion, as that gentleman could not see that there existed any symptoms of pressure, nor any other indication except that the man would die. Either from your own ignorance of practical surgery, or your unjustifiable belief in the ignorance of your readers, or from your hopes that they would only read your slanderous comment, without reference to the case itself, which contains so palpable a contradiction to your remarks, you select this case as a text for a most malicious and false attack upon my character. It is quite sufficient for you that Mr. Lawrence differed from me in opinion; and you extol that gentleman to the skies, and endeavour, proportionally, to degrade me in the opinion of your readers. I say *you* have done this; for you must know, although you dared to put the slander into the mouth of your

reporter, that the whole of it was a gratuitous fabrication of your own. Mr. Weekes, who was appointed house-surgeon by Mr. Lawrence, was the hired reporter at that time, with the sanction and approbation of Mr. Lawrence. Mr. Weekes admitted, before nearly all the medical staff of the hospital, the treasurer, and almoners, that he sent the report of the case as published at page 720, but most solemnly denied that he had uttered one syllable of the scandal which is put into his mouth, or in any way sanctioned the malicious observations contained in your comments; nay, more, Mr. Weekes declared that he had remonstrated with you for abusing his name, and uttering your slanders under the cloak of a reporter: to which your reply was, "that his conscience was too tender."

Your object in thus attempting to rob me of my reputation, needs no observation from me. This one instance will probably suffice to convince your readers of your malice and your falsehood; if they require more, I will refer them to my letter, in the second number of the Medical Gazette.

You next state, that you have not urged, directly or indirectly, that you were sensible you had injured me, and were willing to make reparation. Facts are obstinate things, and I might leave it to your readers to judge by your actions—by your gradually altered tone, and respectful mention of my name, whenever you have of late had occasion to refer to the cases under my care and the operations which I have performed. These I consider as substantial proofs of your wish to conciliate and make reparation; but I possess other proof in support of my assertions. My late neighbour, *your friend*, Mr. Fay, the dentist, repeatedly assured me that you entertained a respect for me, and threw out many insinuations against the principal actors behind the scenes. My reply to that gentleman was, "Sir, I do not ask you whether you are authorised to make this communication to me, but you are perfectly at liberty to tell the editor of the Lancet, that, if such be his real sentiments towards me, he is even more base than I imagined."—Dr. Armstrong, who was called to attend some branches of your family, also assured me *that you were quite satisfied with my public conduct*; for which, as in duty bound, I feel most truly grateful. Lastly, your own reporter, Mr. M'Cristie, about a

twelvemonth since, called on me, in consequence of my remonstrance with Mr. Lawrence for taking money from an acknowledged reporter, and, in conversation, informed me that you had declared to him that all your enmity towards me arose from a belief that I had been a contributor to a subscription raised for the purpose of crushing the *Lancet*; but that, in every other respect, you were perfectly satisfied with my conduct, and entertained a respect for me. Here, then, was a direct avowal of the *pure disinterested motives* which influenced you in reviewing the conduct of a man holding an important public office. The same gentleman, on being informed that I had never contributed one shilling either in favour of, or against the *Lancet*, intimated that he was sure that you would endeavour to make some reparation, and wished me to direct his attention to any cases I wished him to report. My reply was, "that I had never made the slightest objection to the fair and impartial publication of every act of mine, as surgeon of St. Bartholomew's; but that I never would, directly or indirectly, sanction a publication in which I had been so slandered." From that time I have been spoken of decently, have been called by my proper name, and have frequently been mentioned with commendation; and these I consider as substantial proofs of your desire to make reparation.

You next deny that you made application for the notes of my lectures. In my address to the students, I did not state that you had; but I have no hesitation, on the present occasion, in positively affirming that your reporter called upon me, a few days before my address to the pupils, and, after stating that my lectures were highly appreciated, requested me to furnish him with a copy of my notes. "*Qui facit per alterum, facit per se.*" It is true he never stated that he came directly from you, but I had a right to conclude that he did so with your knowledge; and had I furnished him with any manuscripts to place in your hands, I well know the use you would have made of them;—from that moment I should have become an humble tool in your hands, as others have, to their cost. With respect to your request that I would correct the proofs of my lectures, *I never asserted any thing of the kind.* My expression was, that

I was well aware, by correcting the press, &c. that I might gain a certain share of popularity; but this by no means implied that I had been required to do so.

And now, that I have answered your bold defiance, and given you my authorities, and that I have furnished you with proofs of your falsehood and malignity, it remains only for me to express the proud satisfaction which I experience, after so long discharging the arduous duties of surgeon to a large public institution, that my conduct, which has been open to all, has been censured only by a pamphlet whose character for truth is now pretty generally appreciated; and further, that I am now in a situation to be able fearlessly to encounter and expose a public slanderer, who has too long been permitted to send forth his falsehoods with impunity.

I send you this letter because you have pledged yourself to publish whatever I might urge in reply to your challenge, and I now call upon you to redeem your pledge. Fearing, however, that it might be imperfectly understood by your compositor, I have thought proper to send a copy of it to the Editor of the Gazette.

I am, Sir,

HENRY EARLE.

P.S.—There is one other point on which I omitted to make any observation in my letter sent last night. You state that "it is curious that my objections were not made until after the non-publication of my third lecture, and intimate that my vanity was wounded by the omission. At the moment when you penned this paragraph, *you must have known* that you did not possess the materials for publishing my third lecture; that your reporter had applied to me to furnish him with the notes, and was peremptorily refused. As you promise to publish, "without curtailment," all that I shall urge, I desire that this may be added as a postscript to the letter of

HENRY EARLE.

PROCEEDINGS OF SOCIETIES.

HUNTERIAN SOCIETY.

Nov. 4, 1829.

Cerebral Affections.

DR. WHITING related an interesting case of disease of the brain. The pa-

tient was a young lady, and the disease seemed to commence in the frontal sinuses. She had pain about these sinuses, and a bloody fluid was discharged from the nostrils. As the disease advanced, a sense of stunning occurred; on which a tendency to coma and a difficulty of expressing herself correctly supervened. The urgency of the symptoms fluctuated, but the disease terminated fatally.

Examination.—A quantity of pus was found in the anterior lobes of the cerebrum, above the frontal sinuses; but the dura mater did not appear to have given way. The larger quantity of this pus was on the left side. The inner table of the frontal bone was destroyed by caries, and there was a communication between the cavity of the cranium and the frontal sinuses. The dura mater was not adherent to the brain, but the convolutions of the anterior lobe of the left hemisphere were nearly obliterated. Within the substance of the left hemisphere there was a cyst, containing about four ounces of a sort of gelatinous fluid, not so opaque as pus. The cyst was so dense as to admit of being taken out, and no communication could be detected between it and the membranes. The membrane of the frontal sinuses appeared to have undergone thickening. The Doctor conceived that the cyst was an hydatid.

Various cases of head affection were mentioned by other members. Among others,

DR. BABINGTON mentioned a case of abscess within the substance of the brain, and a remarkable feature presented at the onset of the disease. The child was seized with a propensity to run round the room, and cried, "don't stop me; it is so funny!" He also adverted to the case of the lamented Dr. Wollaston, as elucidating the slowness of these diseases, as well as their insidiousness. The particulars have appeared in the Gazette.

MR. CALLAWAY had twice performed paracentesis capitis. In one child, two years and a half old, he operated repeatedly, and with relief; but the child died of measles. The second patient was younger, and died apparently from irritation.

HOSPITAL REPORTS.

HOTEL DIEU.

Encysted Hydrocele of the Spermatic Cord.

A BOY, twelve years of age, was operated upon at the Hôtel Dieu, for hydrocele of the left side, in 1828. He was treated by injection, and left the hospital perfectly cured. Some months afterwards, there appeared in the groin opposite the inguinal ring a small tumor, which was soft, indolent, fluctuating, and without any discoloration of the skin. This swelling seems to have been taken for hernia, for a bandage was recommended. Notwithstanding the use of this, however, the tumor continued to increase; in consequence of which the patient entered the hospital again last month.

A roundish, slightly elongated tumor, as large as a full-sized pigeon's egg, presented itself opposite the inguinal ring. It began about half an inch from this point, and terminated near the epididymus. Although pretty tense, it was fluctuating, and without any change in the appearance of the skin. No shock was communicated to the hand when placed on the swelling while the patient coughed. It could be made to return into the interior of the inguinal canal, but it was perceived to be insulated there. There was a manifest transparency in the tumor. These appearances led M. Dupuytren to regard it as an encysted hydrocele of the cord, and he proposed to treat it by incision.

The operation was performed Oct. 13. The boy was placed on his back, and an incision made into the skin covering the tumor. This incision was made with as much care as in a case of hernia, lest there had been any mistake in the diagnosis, and to avoid the risk of wounding any part of the spermatic cord. The subjacent layers were successively divided, and a jet of lemon-coloured serum announced the opening into the cyst. The opening was enlarged by means of a bistoury and scissors. The finger introduced into it could detect no communication; the serum it had contained was entirely evacuated, and the cavity was filled with charpie, to produce suppuration, and subsequent adhesion of the parietes of the cyst.

The charpie was removed in a few

days, and filled with fresh lint. A moderate degree of inflammation resulted, and to-day (Nov. 11) the wound is nearly cicatrized.—*La Clinique*.

Vesico-Vaginal Fistula.

The following case will be read with interest by those who have perused Mr. Earle's interesting lecture in our last number. A woman, about 30, was admitted into the Hôtel Dieu, during the winter of 1829, labouring under a communication between the bladder and vagina, the result of a long and difficult labour. She was treated by means of the actual cautery; and gained, first, some decided improvement; and, subsequently, obtained a complete cure. Scarcely had the urine entirely ceased to flow by the fistula, when she became impatient of delay, and left the hospital. For some time all went on well; till one day, having made a violent effort in her anxiety to get quickly into a carriage, the cicatrix gave way, and the opening was re-established; the urine flowed through it as before, and all the former evils were experienced.

The patient was examined in the first place, and the situation of the fistula perfectly recognized by the finger; it was in the neck of the bladder, and on the right side of the vagina. By means of a speculum its exact disposition was determined:—it proved to have a transverse direction, and to be formed of two lips, the upper of which extended downwards; and passing a little lower than the under one, thus could be made to close the fistula altogether, or nearly so. This explained the circumstance of the patient retaining the water in certain positions, while in others, as the recumbent, the discharge was involuntary; these conditions depending upon whether the upper lip was or was not applied over the orifice.

In this state of matters, M. Dupuytren resolved to have recourse to the same means which had relieved her before, viz. the cautery. For this purpose the following operation was performed Oct. 13. The patient was laid on her face across the bed, a pillow being placed under the abdomen, and the limbs hanging over the bed.

A speculum was introduced, so as to bring the fistula completely into view, when M. Dupuytren cauterized its edges lightly with an iron, shaped like a small

bean, and heated to whiteness. In the course of the day the patient was placed in a bath, to moderate the pain and inflammation which necessarily followed. From this time the urine ceased to flow by the fistula, the inflammatory tumefaction presenting a sufficient obstacle to it; and up to the present date there has been no return of the discharge by the vagina.—*Ibid.*

GUY'S HOSPITAL.

Compound Fracture — Amputation — Extreme Constitutional Irritation — Death.

JOHN GREENEL, æt. 17, admitted Oct. 10, 1829. This afternoon, when going down a ladder to the engine-room of a steam-packet, he fell, so as to involve his right leg in the gearing of the engine, and before it could be extricated, received several strokes from the engine-beam on his right leg and foot, which produced compound fracture of his tibia and fibula, comminuted, and extending into the joint; fracture of the internal and middle cuneiform bones; partial dislocation of the astragalus; and extensive laceration of the soft parts. There was also great contusion of the leg, knee, and lower third of the thigh.

At 5, P.M. Mr. Morgan performed amputation, removing the leg below the knee by the usual circular operation. On dividing the integuments of the back of the leg, there was a copious gush of previously extravasated blood; and on dividing the muscles, unusually violent spasm of the limb took place. In other respects the operation was not remarkable; two vessels were secured by ligature, the integuments brought together laterally, with the customary dressings, and the boy then put to bed, in a somewhat exhausted condition.

In half an hour copious hæmorrhage took place; the dressings were removed; a third ligature applied to a bleeding vessel, and the stump again dressed; after which, pressure by the hand of an assistant was constantly made on the stump, thereby checking hæmorrhage, and preventing spasmodic movement of the limb.

2d day.—In the night, constant oozing from the stump, but no large bleeding; pain in the limb, with slight spasm; no sleep; countenance anxious and very pallid; pulse 110, with a sharp stroke. Towards evening his excitement greatly increased; the spasms of the limb became so violent as to require some force to retain it on the pillow. Excepting in the limb itself, there are no symptoms of local disease.

Rx Opii grs. ij.

Calomel. grs. ij.—Ft. Pil. h. s. r.

3d day.—In the night he became delirious, spasms of the limb continuing; during the day, he is rational and more quiet, but complains of pain extending from the stump up the thigh, which is swollen. Skin hot and dry; pulse 140 to 150, sharp and irritable, but deficient in power; stomach disturbed by nausea; bowels not open since the accident.

Haustus purgans.

*Mist. Effervesc. cum Tinct. Hyoscyami

Evening.—The high irritability, delirium, and spasm of last night, are returning; there is frequent twitching of the muscles of the upper extremities.

Calomel. grs. ij. Opii grs. ij. h. s. s.

4th day.—In the night, wildly delirious, disturbing the ward by his shouts, and making frequent attempts to get out of bed. He has almost constant nausea, with frequent vomiting of bilious matter. Bowels have been freely open. This morning he is less violent; pulse 120, sharp, with a slight increase of volume; thigh painful, and much swollen, with patches of discoloration, and veins turgid. On cutting away some of the dressings, a thin discoloured puriform fluid escapes. A bread poultice to envelop the stump and knee.

Camph.—4tis horis.

Brandy 4 oz. daily.

9th day.—No material change.

Brandy 6 oz. daily.

10th day.—Less pain; stomach quieted by the brandy.

11th day.—Pain and delirium returned violently last night, but have now subsided, leaving him, however, at the lowest point of exhaustion; pulse scarcely perceptible; skin cold and clammy; features sharpened; face deadly pale; but he thinks he is better.—Died at 12, P. M.

THE LATE MR. WADD.

A MEETING of personal friends of the late lamented William Wadd, Esq. took place at No. 10, Park-Place, St. James's, on Monday, the 2d of November, to consider the best mode of paying a just tribute of sympathy and regard for his memory,—when the following plan was suggested for disposing of a part of his property, and thereby preserving entire a very fine and well-known Collection* of Medical Portraits, consisting of nearly 600 Engravings, as a lasting monument of his taste and diligent research:—

It was resolved by the gentlemen present to dispose of this collection by means of shares, at five guineas each, to be decided by drawing, the number of which not to exceed 200. The money to be paid into the firm of Messrs. Herries, Farquhar, and Co. St. James's-Street, to the account of Messrs. Tegart and Nussey, appointed trustees by the meeting.

LITERARY INTELLIGENCE.

In the press, to be published in January, in 1 Vol. 4to.—The Nervous System, by Charles Bell, F.R.S. containing his Papers read before the Royal Society, with Engravings, and an Appendix of Cases and Consultations, illustrating the Doctrines advanced in the Text.

* The Biographical Catalogue of these prints was published, in 1824, under the title of "Nugæ Chirurgicæ," by Messrs. Longman and Co. Paternoster-Row, and Callow and Wilson, Princes-Street.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

LECTURE IX.

Treatment of Inflammation—Antimony—Mercury—Diet, &c.

LOCAL bleeding, gentlemen, may be employed with advantage in the treatment of inflammation when the urgent symptoms have been subdued by the general loss of blood; or it may be employed alone in cases of a less serious description. In taking away blood by cupping, or by the application of leeches, when we have a choice between them (for scarification, and the abstraction of blood by punctures, are applicable in only a few cases), cupping is to be preferred, as the more efficacious of the two; for we can succeed in getting blood more quickly, and with more certainty, by this method than the other. But there are several parts of the body to which the application of leeches is the more desirable. With regard to their number, I should say generally, and with reference to adults, that it is not worth while to apply less than ten or twelve, and these may be multiplied as the case requires.

You will not, I trust, misunderstand my observations respecting bleeding, as though I recommended that local bleeding should be adopted in all cases of inflammation: in some cases, both general and local bleeding must be practised; in others, local bleeding alone answers every purpose; and there are a few cases in which it is not necessary to take blood at all. You must consider the state of the affected part, and the probability there is that the continuance of the inflammation will produce effects which would disturb the functions of the part. You must also take into consideration the constitution, strength, and the like circumstances, relative to the

patient. When the object is to check inflammation suddenly, you will find it advantageous to adopt general bleeding in a free manner—to take a large quantity of blood, and even to repeat the depletion; but the most effectual way is to bleed largely at once, as the end is obtained with much less expense to the general system than by what might appear a milder use of the lancet. Indeed there is no comparison, if we look to the mere point of debility, as to the effect of continued high inflammation, and that occasioned by the loss of a considerable quantity of blood at once. You will see a patient much more weakened by inflammation going on, than if you cut it short by copious bleeding. It is by no means uncommon to see a patient, in an affection of the head with delirium,—on the subsequent day in full possession of all his powers, if he have been subjected to a full but single depletion; whilst, on the contrary, he would have long remained ill, and the fever continued, if small, though frequent, bleedings had been had recourse to.

There is no one circumstance or symptom which can be laid down as a criterion or index by which to determine the quantity of blood to be taken. Certainly the pulse will not afford it; for in inflammation this may be full, strong, and hard; or, on the other hand, we sometimes find it low and depressed, particularly in inflammatory affections of the head—sometimes small and contracted, but hard and wiry, as in inflammatory affections about the abdomen. As this, then, will not afford a certain criterion, you must look particularly to local symptoms—to the state of the part affected, and its functions; and when you find evidence of active inflammation, you must then freely employ the lancet. It has been said that the state of the blood, as to the buffy coat, may be deemed a criterion for the extent of bleeding; but sometimes this does not exist. I have had occasion to notice the whiteness of the tongue as a symptom indicating the loss of blood to be necessary. It may be well to look to this in cases of in-

flammation, and not to regard it merely in reference to the state of the stomach and intestinal canal alone, but as it respects the system at large.

It is not sufficient in the treatment of inflammation to diminish the quantity of the circulating fluids by the abstraction of blood; we must also make use of means to prevent the introduction of further supplies into the system, by the use of purgatives; and these are to be regulated according to the nature of the case. You employ purgatives first to empty the alimentary canal—to clear out the whole of its contents. For this purpose we give a full dose of Calomel, with extract of Colocynth, or Rhubarb, and follow this up with an aperient draught of infusion of Senna, with Epsom salts, or a dose of Castor oil. You in this way get rid of what was in the intestines, and which kept the bowels in a state of irritation. You then administer neutral salts in small doses, to keep up a continual discharge from the intestines and the mucous surface of the stomach. On some occasions a large—a very large quantity of watery discharge is produced from the alimentary canal; but this is not surprising when we come to consider the great extent of surface presented by the stomach and intestines. The quantity of fluid so evacuated is very considerable; yet you will find persons go on giving purgatives for a great length of time, and to a great extent, who, nevertheless, are afraid of taking away a few ounces of blood from the arm. I have seen *Elatezinum* so given as to produce, by measure, five or six quarts of watery evacuations! When given in such a way, we cannot doubt that they have as great an effect in lessening the quantity of the circulating fluids as the taking a few ounces of blood from the arm. We ought probably to regard the administration of purgatives not only as lessening the quantity of the circulating fluids, but also as promoting counter-irritation, and thus reducing the determination of blood towards the part affected.

In inflammation, the diet must be particularly attended to. It must consist of fluids, or of plain, diluent, mucilaginous, and acidulated drinks, such as plain water, toast and water, barley water, lemonade, or tea. This should constitute the diet of a patient labouring under an inflammation attended with general disturbance of the system. When the case is not so serious, something more solid may be used, as roasted apple, ripe fruit, and toasted bread.

Such are the circumstances to be attended to in the treatment of persons labouring under inflammation: loss of blood, purging, abstinence,—these are the three great means of reducing inflammation. But there are auxiliary aids. In the first place, reducing the increased heat of surface, a symptom which is very troublesome to the patient. We find

that if perspiration be promoted, the febrile symptoms become reduced, and hence attempts have been made to bring on perspiration by the use of such medicines as Nitre, Liq. Ammon. Acet., the alkaline salts, with citric acid, &c. and these are called *Refrigerants*, or cooling medicines, because they take away the heat of the body. But the most powerful medicine of this kind is Antimony, of which there are two preparations well known, as James's Powder, and the Tartarized antimony, or Emetic tartar. These are very powerful remedies, for the emetic tartar does not merely act upon the skin—it also, according to the dose, produces perspiration by exciting nausea, or sickness, and purging; thus it becomes a powerful agent in checking inflammation. If the tartarized antimony be given for the purpose of producing perspiration, a quarter of a grain every four hours will excite it, and keep up a state of nausea;—half a grain produces sickness. When it is thus given in sufficient doses, you will find the action of the venous and arterial system greatly reduced by it, and perhaps there is no better mode of doing this, particularly when its use has been preceded by the more powerful means of bleeding. The pulse is exceedingly reduced in number and force under the state of nausea: in fact, so reduced, that the patient is brought, as we say, almost to death's door. This is particularly seen in the case of persons who go on board ship: they are violently sick—what is called *sea-sickness*—they lose all power, and lie as if they were dead. In this way, then, emetic tartar acts, by directly checking inflammatory action. Of late, this medicine has been used in larger doses than we are accustomed to give it, more particularly by the Italian physicians, who have observed its powerful effects, and have classed it among the *contra-stimulant* or *antiphlogistic* medicines. *Contra-stimulant*, gentlemen, is a Latin phrase, which signifies that which is opposed to, or designed to check stimulus; and inflammation being the result of stimulus, it therefore means, that which reduces or lessens the cause of inflammation. *Antiphlogistic* is derived from the Greek, *φλογίζω*, to burn,—to inflame, and therefore means the same as the Latin, that which is opposed to or designed to check inflammation. This medicine, that is, emetic tartar, is made use of by the Italian physicians, not in grain or half-grain doses, but to the extent of a scruple to a drachm and a half, and they say it does not, in these quantities, cause either vomiting or purging, and though frequently the first dose does so, yet after this the stomach receives it without repugnance, and in many cases it reduces inflammation without producing any evacuation, either from the stomach or bowels. I have in many cases tried its effects in this way, by giving a grain and a half, repeated

every two hours, and after eight or ten doses I have increased it to two grains; and in these instances I have found its effects to be as above described. In many cases of inflammation, particularly of the chest, and in violent phrenitis, its exhibition in this way has saved the loss of blood to a very great extent.

Another remedy of very considerable power in the treatment of inflammation, though it operates in a very different manner, is *Mercury* in its different forms, especially *Calomel*. It has long been ascertained by general experience, that the exhibition of calomel, after direct depletion, has a favourable effect in checking the progress of inflammation, in expediting the recovery of the patient, and, in preventing those changes of structure which frequently result from inflammatory action. Thus, we may say, that after employing the lancet freely, and after the complete emptying of the alimentary canal, the administration of calomel in doses of from two to three or five grains, every six or eight hours, has had a much better effect than if the general plan had been pursued. Upon observation, you will find that it has the power of changing the nature of the actions, and thus expediting recovery. In this point of view, it will of course be found an interesting matter to inquire how this end is accomplished. In the exhibition of calomel in inflammation of the iris, we see how its effects are produced. The inflammation of the iris is accompanied by effusion of lymph upon its surface. We find that by the exhibition of calomel, more particularly when the mouth becomes affected, the lymph is quickly absorbed. When I speak of calomel, I of course speak of mercury in general. Here then is clear evidence that it is by arresting the formation of lymph, and promoting its absorption, that these effects are produced. But the effect of this remedy is not confined to that particular form of disease; I only mention it as affording a proof of its effects in causing absorption, and as rendering it probable that in other cases, particularly in affections of the larynx and trachea, where an adventitious layer of coagulated lymph is deposited, mercury effects its removal by this way. It is not improbable, then, that mercury has the power of arresting that morbid action of the capillary vessels, which produces a change in the structure of the parts, when inflammation is going on to any extent. This, however, is a point which lies open for future observation; the exhibition of the remedy has not been tried in a sufficient number of cases, nor its effects been followed up by pathological observation, so far as to enable us to determine its exact mode of action; still there is great reason to infer that the effects which I have just described may take place generally.

These means taken together constitute what is called the *antiphlogistic treatment*—that is, treatment on a plan calculated to counteract the inflammation: and, when we speak simply of the general management as to diet, we call it the *antiphlogistic regimen*.

Although it may be stated generally that local applications are of much less importance than general means, in the treatment of inflammation, yet they are often useful as auxiliaries, and in many instances produce a comfortable effect on the patient's feelings. The increased heat of the part has naturally led to the employment of cold. We find, indeed, that the application of cold to the human body has the power of arresting hæmorrhage from wounds, and the loss of blood from other causes, as well as of checking inflammation. In fact, if we choose to apply cold in a considerable degree, and for a great length of time, it not only reduces the vascular excitement, but destroys vitality altogether. Various applications have been made to the inflamed part, to reduce its heated temperature: these consist of lotions, or washes. They are used by taking soft linen folded together, dipping it into the fluid, then laying it on the part, and frequently renewing it. The effect of this application depends, not on the mere circumstance of applying cold, but upon its being applied in such a way that the fluid may be evaporated from the surface of the part. Evaporation is a very powerful mode of producing cold. Hence the liquids used are frequently called *evaporating lotions*. It is of importance that you should take care, when you use these liquids, that they are so employed as to admit of evaporation, and not as I have frequently seen them used, the affected part being placed under the bed-clothes, in a kind of warm-bath. When thus employed, it is not surprising that nothing is effected by the application. For the purpose of producing cold in this way, we used cold water, iced water, vinegar and water, rose water, and very often a solution of sugar of lead. This last has been a very favourite remedy in reducing inflammation, and has been supposed to produce its effects by some sedative quality which it possesses. Thus we continue to use Goulard wash, or the saturnine lotion, though we do not regard it as deriving its efficacy from this circumstance. Sometimes other things are added to increase the evaporation. Spirits of wine may be employed in conjunction with rose-water, in the proportion of two ounces to six. When we wish to reduce the temperature of the part still further, we apply ice to it, roughly powdered, and wrapped in a cloth, or put into a bladder. Such application is, of course, at a temperature of 32 degrees; and if this be kept on until it is melted, the effects are very striking, particularly when applied to the head, in cases of determination of blood to

that part. If we apply cold spring water in a bladder, and renew it, we shall find that the temperature of the head will soon be much reduced. Even when considerable excitement exists, the patient will begin to find the cold very uncomfortable, and wish it to be removed; in fact, it soon produces such pain that he cannot endure it longer. An aged patient requires warmth; and there are many instances where warm applications are found more beneficial, as well as more comfortable to the feelings of the patient, than cold ones, and we are of course accustomed to accommodate the remedies employed, as much as we can, to their feelings and wishes. For this purpose we use warm fomentations, as flannels dipped in warm water, sometimes in medicated water; these being laid upon the affected part, and renewed as required. When fomentations are applied to a considerable surface of the body, as the chest, and decoction of poppies or camomile flowers are employed, they may be put into a rough towel, and laid upon the part. They will thus produce warmth and general perspiration over the whole frame. There is no invariable rule which we can lay down for the choice of warm or cold applications; but we may say generally, that cold is best in superficial inflammation and in the incipient state; but when it is fully developed or seated under the surface, not in the skin, warm applications are best. For local applications, we find a greater variety of substances used than I have now mentioned, but I do not believe that any one of them acts in the way generally supposed. We know, indeed, that opium will operate through the cuticle, if rubbed in; but such a thing as an infusion of herbs in hot water is not capable of this.

When new diseases are produced, those which existed previously become diminished, or entirely disappear. If a person has a violent inflammation in the urethra, and the testicle become affected, the former disappears. If a child has an inflammation of the eye, and the ears break out into sores, the former gets well. It has been attempted to imitate this process of nature by producing an artificial or new disease, to lessen that which already existed. This is called *counter-irritation*, and sometimes *revulsion*. Counter-irritation means opposed to irritation—revulsion is from the Latin word *revello*, to draw away; it is thus used under the idea that the new disease draws away that which previously existed—the words, therefore, are of analogous meaning. This object is mostly attempted to be accomplished by blisters; but these are not the only means employed. It has lately been proposed, by Sir Anthony Carlisle, to produce it by dipping a piece of metal in water of a given temperature, and laying it on the part; and this we know will produce blisters as

effectually as if the application were made with Spanish flies. The liquor ammoniac will produce a blister equally as boiling water, and may be used to produce its effects instantaneously. In order that we may have a chance of reducing existing diseases by this means, it is necessary that the new irritation be more powerful than that already existing. In a case of active inflammation in its full development, which has not been checked, the disease cannot be stopped by blisters; they will only add to the irritation, and increase the patient's suffering. Blistering, then, is not to be employed while local irritation is at its height, but after depletion and the other means already described have mitigated the local disturbance, this will assist in its removal. Blisters are also applicable when we wish to recal inflammation to a part which it has quitted, to fix itself on another part more important; especially on some internal organ, as in cases of gout and rheumatism. It may be doubted how far this is beneficial where inflammation has passed from an external part to an internal one. It may be best to attack it vigorously in its new quarters.

The means specified as proper to be employed in cases of local inflammation, may be continued and repeated until the inflammation is removed, or a milder course may be adopted, according to the circumstances of the case, till the functions of the part are restored; and the patient may gradually be permitted to return to his ordinary avocations.

But it will be necessary still to pay attention to the bowels and diet. Mild opening medicines should be administered, and the diet should be light, and in small quantity. Patients place a considerable part of their delight in eating and drinking; and when they have been for some time deprived of this pleasure, they wish to get back to it, and recommence stuffing as soon as they can. They have a longing after the "flesh-pots;" and the medical man often seems to think the enjoyment of them to be as important as does the patient himself. But it is very important that this should not be allowed, as it frequently occasions tedious convalescence, and often causes relapses. Dr. Baillie has stated, that almost all relapses in cases of inflammation may be attributed to a premature return to the ordinary habits of eating and drinking. If you treat cases of acute inflammation according to the principles laid down, you will find that you get rid of the disturbance in the part, and that it returns to its natural state. If, however, it be treated more mildly—if persons are afraid of taking a little blood in cases of acute inflammation, it will frequently happen that after the active stage has been somewhat subdued, the disease will pass into a chronic form. This will not always prove

the case to have been badly treated, but it generally shews that the treatment has been neglected or improperly conducted.

In other instances inflammation has been chronic from the beginning; that is, marked by less active symptoms than in acute inflammation. Although chronic inflammation is not marked by the same violent symptoms, or active sympathetic disturbance in other parts, it is nevertheless the same in kind as acute inflammation, and must therefore be treated in the same manner. It is a degree of active inflammation modified in proportion as its effects are violent or moderate. Inasmuch as the symptoms are less violent, it is not so necessary to take blood; indeed, a great abstraction of blood is by no means requisite in cases of chronic inflammation. Still we see many instances of chronic inflammation where we must take blood from the arm; and in patients of plethoric constitution, or where the inflammation is seated in some important part, it will be necessary to do so, else it will not be brought to an end for some weeks, or even months. We must attend to the patient's particular habits, and other circumstances, to determine the quantity of blood that must be drawn.

Counter-irritation is very applicable in cases of chronic inflammation, and we employ more active modes of producing it than in cases of acute inflammation. A more considerable and permanent means of promoting this than the application of blisters, is by rubbing in an ointment, composed of emetic tartar finely powdered—one part of the tartar emetic and three parts of lard. Rubbing this in night and morning produces inflammation of the skin, with the development of large pustules, much resembling those of small-pox. Setons, issues, and moxa, are other modes of effecting counter-irritation.

The regulation of the digestive organs is of much consequence in the treatment of chronic inflammation. We must clear out the alimentary canal, and adopt such means as will keep up an active though not violent discharge from the bowels; that is, without producing purging. There are a great many medicines which have the effect of purging, but in different cases we must select those which are most applicable. In such cases as we speak of, the neutral salts, at short intervals, will suffice, as we do not want in chronic inflammations to reduce the powers, but merely to obviate that disturbance in the system which the retention of feces would occasion, and to prevent accumulation. There are substances which act particularly upon the large intestines, such as aloes and colocynth, which we call *Eccoprotics*, from *εκ* and *κωπος*, dung, or medicines which clear out the dung. These, in moderate doses every day, or every other day, are to be employed, and with them may be

combined mild mercurial medicines, for the purpose of altering the state of the secretion in the alimentary canal. We see that when the colour of the feces is unnatural, the exhibition of mercury, in small doses, alters it, through some effect upon the liver. Calomel or blue pill, with compound extract of colocynth, or extract of rhubarb, are useful. Calomel is one of the best remedies, in small quantity, for this purpose; and, therefore, it is the basis of a number of quack medicines, under the names of "stomach pills," "dinner pills," &c. which are nearly all composed of calomel in conjunction with aloes.

When the tongue is very foul and loaded, and the discharges from the bowels are dark and unnatural, it is frequently advantageous to give an emetic, or to administer antimonials, in small quantities, as a few grains of James's powder, with calomel or blue pill, at night, and infusion of senna, with salts, in the morning. We cannot altogether explain the advantage of combining them, but we find when they are combined together they produce beneficial effects of which they are not capable when given separately. Thus, then, we exhibit purgatives in various ways.

After clearing out the alimentary canal, it is expedient to administer mercury in the *alterative* form, that is, in small doses, continued for some time. Five grains of the blue pill, or of Plummer's pill, or a grain or two of calomel, may be administered at bedtime every second night, and some aperient medicine may be given in the morning. I have mentioned aloetics: and you may give the compound decoction of aloes in the middle of the day, or a little before dinner. In elderly, or debilitated persons, you should generally select warm purgative medicines: the *beaume de vie*, as it is called, is a very good one; and under such circumstances, the tincture of rhubarb, with tincture of senna, also forms a good purgative.

It is absolutely necessary, in the treatment of these cases, to attend to the diet of the patient; it is quite as essential to regulate that as to determine the surgical treatment. Indeed, if you content yourselves with prescribing the surgical means, and leave the patient to regulate his diet, he will do more harm by what he puts into his stomach than you can do good by the medicines you administer; in fact, you will be beaten. During the existence of such inflammation, fermented liquors are improper; and animal food should only be taken in small quantities, and at stated periods. Broths, bread and milk, and the various farinaceous articles, are such as should be taken; that is, what is between the low diet of fever, and the full diet of health. When the local excitement is completely stopped, and the general disturbance has ceased; when the tongue is clean, and when, in fact, the pa-

tient is well, he may return to his common diet, but not before.

In that class of affections called spontaneous, or which are said to come of themselves, when they occur in nervous persons, of sedentary habits, and who have lived in bad air, we must do something more than adopt these means for relieving them. The necessary remedies, however, gentlemen, I fear you will not find in the *pharmacopœia*; there are three things which do not belong to the *materia medica*, but which to such persons are of the greatest importance—residence in pure air, exercise of body, and tranquillity of mind.

LITHOTRITY.

To the Editor of the London Medical Gazette.

SIR,

AMONG the most useful of the improvements introduced by Baron Heurteloup in the operation of lithotritry, are the means he has adopted for insuring the favorable position of the patient, and fixing the instruments without the aid of an assistant, while their action is proceeding. I have translated the chapter of his unpublished work, in which he treats these two subjects in detail. The accompanying sketches, though slight, will, I hope, assist in making the description intelligible.

I have much pleasure in forwarding this chapter for insertion in your journal, as being entirely practical. I trust it will be of service to such of your readers as may wish to study the art Baron Heurteloup has come to England for the purpose of demonstrating.

I am, Sir,

Your obedient servant,

J. RUTHERFORD ALCOCK.

Westminster Hospital,
Nov. 21st, 1829.

On the Position of the Patient and Surgeon during the operation, and the manner of fixing the instrument during its action against the Stone.*

Now that we have a precise knowledge of the end proposed in the construction of each of the instruments destined to

* It must be remembered that this paper is a chapter of M. Heurteloup's work. This will explain the manner in which it commences, as I have thought it right to adhere closely to the text of the author.—J. R. A.

destroy calculi in the bladder, and that their structure, mechanism, and action, are understood, let us consider, before we apply them to patients, or, rather, before we think of manœuvring them, the position in which we ought to place our patient, and what are the means we should employ to fix and retain the instrument about to be used during its action on a stone.

In the same manner as I have materially altered the instruments employed in destroying calculi, in proportion as they presented different forms and sizes, so these variations in the stones will furnish us with new indications to be fulfilled in relation to the position to be given to the patient, and the mode in which the instrument is to be held.

We have seen that when the stone was of small volume, the action of the *perce-pierre* was sufficient; but when the size was increased, and too large to be broken by one or two perforations made by this instrument, it became necessary to have recourse to a system of excavation; but whether the system of perforation is sufficient, or whether we resort to that of excavation, we should of course adopt those means of destruction we think best adapted to the cure of the patient.

When the stone is small we ought to place the patient on a common bed, and employ the hand only in destroying it; or a bow, put in action by means of the *chevalet*. When the stone is voluminous, and requiring the action of the *evideur*, we should place our patient on a particular bed, and fix the instrument in a more convenient manner. The play of the *evideur*, which joins to the perforating action from before backwards, a lateral motion, requires great steadiness, in order that its action may be satisfactory. Thus the precautions taken would be in exact proportion to the difficulty of the operation.

We will begin, then, by considering the position of the patient previous to the commencement of an easy operation; that is to say, in a case where it is judged proper to operate with the *perce-pierre* put in action by means of the *chevalet* held by an assistant.

On the Position to be given to the Patient when operated on by the perce-pierre, supported by the chevalet, and held by an assistant.

When it is ascertained that a patient

is afflicted with a small stone, which can be easily crushed by the *perce-pierre*, it may be sufficient to place him on an ordinary bed, and employ a kind of vice for the purpose of holding the instrument, in some degree similar to the lathe employed by the watch-makers; and retained in a proper position by the hand of an assistant. We will now consider the best manner of making use of these means.

We should endeavour, as much as circumstances will allow, to place the patient on a hard bed, neither very low nor very high, in order that the surgeon during the manœuvres, and while he is turning the drill, should not be obliged to bend if the bed be low, nor by its being too high have the movement embarrassed and uneasy. The patient should be so placed on the bed as to have the left leg resting on the mattress, and the right supported on a chair; the pelvis would thus be brought to the edge of the bed. This part of the body must be raised by a moderately firm pillow. The body should lie flat, the head and shoulders only slightly elevated. Such is the position which ought to be given to the patient on a common bed. If we have a sofa without a back we might operate on it with sufficient facility. In that case the patient is desired to lie down easily and naturally: the pelvis is raised, and he is requested to keep his thighs separate, and his legs slightly flexed. The patient thus placed, so that his thighs and trunk join nearly in a right line, the surgeon may proceed with the operation*.

The operator may, in introducing his instrument, if the patient is lying on a

common bed, with one leg on a chair, as has been described, place himself immediately opposite. This is the most favorable position. If the patient, on the contrary, be placed on a sofa, so that his feet are both on the same level with his body, the surgeon ought to introduce his instrument from the side: this is a less favorable position. The instrument being introduced, if it was done while standing opposite the patient, the operator ought now to come to the right; if, on the contrary, he introduced it while standing at the right, he ought to remain in that position, to seize and break the stone, effecting the manœuvres which we shall indicate presently when we treat in detail of those which the *perce-pierre* requires.

As soon as the surgeon has succeeded in seizing the stone between the three branches of the *perce-pierre*, he should estimate, by the length of the stem of the perforator, if the stone be small enough to allow of its being crushed by the pressure of the head of the drill, with the movement that may be given to it by the hand. He ought to endeavour to do it; and if he does not succeed, this rotatory movement which he gives to the drill with his fingers, will serve as an experimental essay, shewing him that it will turn with facility when he wishes to rotate it with the assistance of the bow; but to employ the bow, he must complicate his apparatus by the instrument which we have called *chevalet*, and the construction of which we are now going to examine before explaining the manœuvre.

The Chevalet.

The *chevalet* is an instrument destined to effect the following purposes. 1st, that the *perce-pierre*, being charged with the stone, may be held by the hand of an assistant; 2d, that the operator may, by means of a bow, give a quick movement of rotation to the perforating

* When the *chevalet* is used, it is required that the pubes should project a little, and that the thighs be not bent upon the body; for the bow, to which we are obliged to give a position, making it at right angles with the axis of the body, cannot act, or at least very imperfectly. It is therefore necessary to pay strict attention to this precept—that the body and the thighs should, as nearly as possible, be in a straight line.

drill; 3d, that the drill, in proportion as it perforates, should be pressed upon the stone. Let us now see how these indications are fulfilled by means of the chevalet. We will first examine its construction.

Construction of the Chevalet.—It is composed of two pieces, which, combined, fulfil the object for which it was constructed. We call the first piece the support* (fig. 1); and the second the repoussoir (fig. 2); from the use to which each piece is destined. The support presents a curved part (A, fig. 1), and a straight piece (B). At the top of the curved portion is a square passage (C), which is destined to receive *with facility* that part of the instrument which is equally square and adapted to it, and which we have called l'armure†. The straight part of the support is exactly squared, from eight to ten inches in length, two lines and a half in thickness, and from six to seven in width. An oval ring is observed at that part where the straight and curved pieces unite (D); which is attached to it, and is intended to give the assistant the facility of firmly holding the instrument with the right hand, while the surgeon is effecting the perforation of the stone.

The repoussoir is rather more complicated, and presents two extremities—an inferior and a superior. At the inferior extremity there is a hole (A, fig. 2), which is destined to receive the straight part of the support, which passes through it easily. A screw is placed below, so as to fix at will the repoussoir on the support.

The superior part of the repoussoir presents a kind of tube (C), in which there is a spiral spring. In this tube there is a little steel pin (D), which is so adapted that the pushing it into the tube allows the spring to act; and as its action tends to push it out of the tube, it necessarily presses the central stem to which the drill head is attached, forward, as it gradually sinks into the stone. A screw (E) placed above the

repoussoir, fixes at will the steel pin, which has at the external extremity a hollow, for the purpose of receiving the stem of the perforator. A little catch exists in the superior part of the pin, in order that, when the screw is loosened, the pin may not escape from the tube, notwithstanding that it is sufficiently free to obey the impulsion which the spring will naturally give it. Such, then, are the two parts which compose the chevalet. Let us now see in what manner they ought to be used.

Mode of using the Chevalet.—We have described the operator as having seized the stone, and that, finding it necessary to perforate it, he is obliged to have recourse to the chevalet.

The assistant should have disposed it so that the "support" and "repoussoir" should be separated, and have pressed the steel pin upon the spring, and fixed it there with the screw for that purpose.

The stone being seized and fixed in the perce-pierre, the surgeon should hold his instrument in the left hand while he takes the support with the right, and adjusts it. Holding the instrument and the support in position with the right hand, he ought then to take the repoussoir with the left, and, in the relation to the support which we have already described, adjust the extremity of the stem of the perforator with the hollowed end of the pin, and free the screw which holds it; so that, obeying the impulsion given to it by the spring, it may force the perforator against the stone, keeping it in constant contact during the whole of the perforation.

This done, he assures himself once more that the drill turns easily; and confiding the instrument thus disposed in the chevalet to the hand of his assistant, he takes the bow in the right hand, near the handle, which he holds between the palm of the hand, the middle, ring, and fourth fingers, whilst he seizes the cord between the thumb and indicator, and places it over the pulley of the instrument. Grasping this pulley with his left hand, without allowing the cord to slip, he seizes the opposite extremity of the bow at about three inches from the hook; holding thus, with the left hand, the extremity of the arch of the bow and the cord, which he is careful to retain stretched, in order that it may not slip from the groove of the pulley, he leaves the handle of the bow which he held in his right hand,

* The support is evidently for the purpose of supporting or maintaining the instrument; while the chief use of the other piece, the repoussoir, is by its spring, to repel or push forward the drill upon the stone.—J. R. A.

† All M. Heurteloup's instruments have a steel piece, squared sufficiently strong to resist the pressure of the screw, and yet allow the instrument to be firmly supported. It is this steel cap or envelope, for the purpose of guarding the instruments, which are of silver, from too violent pressure, to which M. Heurteloup has given the name of armure.—J. R. A.

and takes hold of its end, and with this hand curves the blade, whilst the cord, seized between the indicator and thumb of the left hand, is brought upon the hooked extremity of the bow.

The blade is thus held until the surgeon has adjusted the loop which is at the end of the cord on the hook of the bow. The operator, in holding his bow with the left hand, which he keeps in position, seizes the handle with his right; thus his left hand grasps the mass formed by the instrument and the chevalet, at the place where these two parts of the apparatus join by means of the hole which is formed at the superior extremity of the curved portion of the support. The assistant thus holding the apparatus composed of the instrument and the chevalet, and the surgeon also grasping it with his right hand, holding with his left the handle of the bow, every thing is disposed for the perforation of the stone as soon as the rotatory movement shall be given to the drill.

The surgeon ought to commence the perforation of the stone by giving to the bow first a very gentle movement, in order that the drill may make its impression on the unequal surface of the stone; and this beginning once made, he may proceed with more vigour, avoiding of course any shock, as that would fatigue the patient. The arm alone which holds the bow should move; all the rest of the body should be without motion, and the sweep of the bow should be the full length of the cord.

As soon as the drill has pierced into the stone as much as the adaptation of the instrument will allow, the operator should dismount the bow and the pieces of the chevalet in the same order in which they were put together; to do which, the assistant should continue to hold the instrument. The surgeon then takes the extremity of the bow with his left hand, leaving hold of the handle which he held in his right, and seizes with it the extremity of the blade, which he curves, while with the left he grasps the cord and unfastens it with care*.

* During the whole of this time the operator should be particularly careful to keep the bow exactly at right angles with the axis of the pulley; for if he were to incline it before the cord was unfastened, the string would fly from the groove of the pulley, and give a shock to the instrument by the sudden rise of the end of the bow, which would be extremely painful to the patient. This ought to be borne in mind, not only in relieving the bow, but also in fixing it.

After this, the screw which holds the repoussoir fast upon the support is loosened. The repoussoir is taken away first, and the support follows.

This effected, he continues the appropriate efforts for seizing the fragments of the stone, if the stone has been broken by the previous perforation, or to retake the stone if it has only been perforated. If there only remain fragments, they may be broken by the pressure of the head of the drill; if the calculus be yet entire, though perforated, it will be again necessary to make use of the chevalet, and renew the series of manœuvres which the destructive process requires.

During the whole of this manœuvre, the assistant ought to place himself immediately in front of the patient; which he will find he can do with great facility, whether the patient be placed on a common bed, as we have described, or on a sofa without a back or ends. In this last case, the patient should be placed sufficiently near the end to allow the assistant to hold conveniently the chevalet, and without being in a constrained position. He ought to be particularly careful to keep the extremity of the instrument, which grasps the stone, in the middle of the water with which the bladder is injected, and avoid carrying it towards the inferior portion of the bladder; and especially not to allow it to be pulled towards the neck, for the branches of the instrument would thus be in contact with that part of the bladder, and the patient would experience a disagreeable and painful vibration.

He should also be particularly attentive to hold in readiness for the surgeon that part of the chevalet called the repoussoir; and each time the operator resigns this part to him, to draw back the steel pin upon the spring, and tighten the screw destined to maintain it in this situation; so that the surgeon has nothing further to do, when he has adjusted the extremity of this pin, than to loosen the screw which holds it back, in order that the spring may act upon it.

Such is the manner of effecting in the shortest way the combined movements of the operation of lithotritry, as far as regards the use of the chevalet.

It will easily be seen how possible it might be to obtain a great saving of time and of movements, by a better constructed apparatus, which should

abridge as much as possible the fatigue which the operator and patient must both experience during the whole of the time occupied by these manœuvres of the chevalet, which evidently possesses a *simplicity* somewhat complicated.

This means of destruction is the first which has been used. We are far from contending that it may not be usefully employed, but only in simple and easy cases, where the calculi may be crushed by the perce-pierre: to these the chevalet has been very usefully adapted. But if with the means now before us, we are enabled successfully to treat these cases, science still requires more, in proportion as the difficulties increase. The patient placed upon a common bed, and the instrument supported by means of the chevalet in the unsteady hand of an assistant, may suffice, it is true, when the stone can be broken up by the action of the perce-pierre, two or three times repeated; but when the stone is of larger size, and requires the more rapid and vigorous action of the evider, these means no longer suffice, and can only, if they are employed to stones of a certain size, purchase the cure of the patient, when such is the result, by a patience which nothing can disturb; in fine, by a slow operation, often repeated, and always painful.

As we have found the perce-pierre insufficient in cases where the stone was more than eight or ten lines in diameter, so have we also come to the conclusion that the position of the patient on a common bed, and the instrument put in action by means of the bow held in proper position by an assistant, is equally imperfect. We have thought more was required, and concluding that though in easy and simple cases, the surgeon could operate with success, notwithstanding the inconvenient position of the patient, and the necessity of operating in a constrained and bent posture, which renders the movements awkward and difficult,—in spite of the mobility of the instrument destined to break up the calculus, the action of which, in some cases, becomes pernicious to the organ, the operator ought in cases of greater difficulty, for the sake of his patient and of science, to have recourse to means more certain and perfect in their action. These were the considerations which induced us to construct the apparatus which we have

called *lit rectangle*, or rectangular bed, which is destined to enable both patient and surgeon to be in the most favourable position, and that the instrument, charged with the stone, should be immovable during its perforation.

We will now pass to the examination of this new apparatus, one which we always use, of whatever kind the operating instruments may be, perce-pierre or evider; because it offers greater chances for the operation being performed without pain, and also on account of the greater rapidity with which it can be done, from the more energetic action of the instruments on the stone, and the greater scope it gives to the manœuvres of the surgeon, by an easy, unembarrassed position.

Lit Rectangle.

I have called this apparatus a rectangular bed, because the pieces which form the principal part of it, when we look at it from the sides, present the figure of a right-angled triangle; and, in fact, this bed cannot be constructed to fulfil exactly all the indications which the operation for the stone demands, when performed in perfection, unless it presents laterally the figure of a right-angled triangle, which is here observed.

The “*lit rectangle*” is an apparatus on which the patient is submitted to the operation, with all the favourable chances for success which a comfortable position for the patient—a perfectly convenient one for the surgeon—and the complete immovability of the instrument during the operation—can afford; to which may be added, the promptitude with which the instrument, charged with the stone, may be put in action without requiring any assistant.

Such is the problem we wished to resolve in constructing the “*lit rectangle*.” Let us first explain the mechanism as far as it concerns the position of the patient.

Construction of the Lit Rectangle.—Three pieces of wood joined (A B C), form each of the two sides of this bed, representing two right-angled triangles. These two triangles are united in front, towards the right angle of the triangle, by a very strong transverse piece of wood, D D; the two shorter sides, A A, of each of the triangles, are joined to each other by two transverse pieces,

which form the bottom for the bed, and which are not seen in this figure: to support the two smallest sides of the triangle, C C, another cross piece is observed, E: the two great sides, B B, hold equally by another cross beam, G.

At the extremity of the pieces which form the long side of the triangles, two holes are to be seen, H, which are destined to receive the two extremities of a cross piece, I, which forms the superior part of a quadrilateral assemblage, K K, serving to sustain the posterior part of the bed, when it is desirable it should rest upon the angle formed by the shortest side, C, and the longest, B, as the figure represents it: if, on the contrary, we wish the bed to rest flat on the hypotenuse of the triangle, this quadrilateral piece, K K, being moveable, and capable of being folded beneath, permits the bed to be lowered. This folding of the quadrilateral piece is rendered easy by unfastening the bar, M, which also is moveable, and which is attached by means of a bolt to the middle of the transverse piece, G, which unites the two long sides of the triangle. It will be seen that when we unfasten the bar of the lower cross beam of the quadrilateral assemblage, K K, the two pieces fold one upon the other, and allow the bed to lie on the long side of the triangle, B: let us bear this in

mind, for we shall have to allude to it when we study the manœuvring of the "lit rectangle."

A small mattress is seen on the frame work, O P, the anterior part of which is placed flat, and the posterior portion, Q, is raised by a sort of wedge or desk of wood, R, which, by being made to move forward or backward, allows the inclination of the mattress to be adapted with ease to the bodies of the different patients. The line of inclination of this wedge should be *exactly parallel* to the long side of the triangle.

In the front of the frame, and below the cross piece, D D, which joins the two right angles of the triangle, two moveable pieces of wood may be observed, S S, so managed as to be lengthened or shortened as may be required, and which have attached at their extremities two slippers, U U. These two pieces are received through a passage formed for them, and secured at any point by screws.

At the anterior extremity of the pieces which form the middle sides of the triangles, a copper button may be observed, X, to which is attached by a button hole, a leather strap with a buckle at the end.

At the angle made by the pieces which form the long and middle sides of the triangles, two handles are observed, Z Z, by means of which the bed may be

lowered at will, so that it rests upon the great side of the triangle, or raised until it rests upon the angle formed by the short and long side.

This, then, is the manner in which the lit rectangle has been arranged: let us now place the patient upon it.

Of the Position of the Patient on the Rectangular Bed.

After having laid a napkin, N, on the front portion of the mattress, the patient is placed so that the nates rest on the anterior edge of the bed, and the head and shoulders are raised (by the inclined plane produced by the wedge-formed box, of which we have already spoken) and the feet placed in the slippers. The patient thus placed is in the position most favourable to the perfect performance of the operation, instead of his unsteady and inconvenient posture when on a common bed, supported by pillows and cushions. Thus, therefore, the advantages to be procured by the lit rectangle, with respect to position, must be certain and evident. We now come to the description of that part of the apparatus destined to fix the instrument, and to which we have given the name of "*Support fixé*," or fixed support, to distinguish it from the "*Support mobile*," or moveable support, with which we are already acquainted, as a part of the chevalet.

The Fixed Support.

This support is destined—1st. to hold the instrument charged with the stone with sufficient steadiness to maintain the extremity of the instrument in the centre of the fluid with which the bladder is filled; 2d. that by this steadiness the excavating instruments may be employed*; 3d. that the action of the perce-pierre may be rendered more energetic and prompt, at the same time that it is easier for the patient; and, 4th. that the surgeon may perform the operation without requiring an assistant.

Construction of the Fixed Support.—Nothing can be more simple than this contrivance: it is a curved flat bar of steel, which moves with great facility in the groove cut through the transverse

bar (DD), which is on the anterior part of the bed. This bar of steel (33) becomes fixed and immoveable by the turning of a screw, the handle to which (4) is placed at the right extremity of the cross-piece (DD). When the screw is unturned, the support becomes again free and drops, the head resting on the cross-piece (DD). At the extremity or head of this support is a groove, accurately filed (5), to receive that part of the instruments already described as the *armure*; a small screw placed in the side of this groove is adapted to press upon the armure of the instrument, which is thus immediately rendered immoveable.

Of the manoeuvres of the Lit Rectangle and Support Fixé.

The rectangular bed only requires to be altered in its position, or "manœuvred," under very rare circumstances—such as when a fragment of stone is placed below the neck of the bladder, in patients where this part is very deep, as in emaciated subjects, and escapes from the researches of the instrument, which cannot seize it without a strong plunging motion; and the seizure of a stone in this manner is extremely painful to the patient, besides that the manœuvres we are obliged to make with this view are often useless. The inconvenience resulting from this circumstance is obviated by considerably elevating the pelvis of the patient, so that the fragment may change its position from below the neck, and fall into the posterior part of the bladder. This elevation of the pelvis is effected by lowering the bed, so that it rests on the long side of the triangle. In this manner the position of the patient is gradually and gently changed; the pelvis is elevated, notwithstanding the body is on a horizontal plane; and a research, which might otherwise be troublesome, attended with pain, and unsuccessful, now becomes easy and favourable in its result. When the patient is thus lowered, it is necessary to take care that he does not slide, by passing a belt round the back of the neck, bringing it over the shoulders, and attaching it to the buckle which has been described when treating on the structure of the bed. This is all that relates to the manœuvring of the bed, and it will be seen that it is confined principally to those rare cases where the fragment is lodged below the

* A stone cannot be submitted to the action of the evident instruments without being thus steadily fixed.

neck of a deep bladder, and inaccessible to the branches of the instrument when the patient is in the ordinary horizontal position. It is sometimes desirable to raise the pelvis considerably, in order to seize a large stone: in this case the inclination of the bed would be useful, and tend to save the patient pain. We now pass to the manœuvre of the support fixed.

Compared to the long and repeated manœuvres of the chevalet, those of the support are very simple.

When the surgeon has introduced his instrument (which he may always do while placed conveniently in front of the patient), and seized the calculus, he carries the extremity of the instrument grasping the stone into the middle of the fluid contained in the bladder, holding his instrument in his right hand, and *without either raising or lowering it* he grasps the support with his left, and raises it to the level of the armure of the instrument, which will be thus received into the groove of the support, which is held in position by the left hand, while he turns the screw and fixes it with the right: to fix the instrument he has now only to screw the head of the support closely upon the armure. Thus, then, the raising the support to the level of the instrument, and turning the screw upon the armure, completes the whole manœuvre necessary to enable the surgeon to apply the bow.

Here are all the details necessary for the full comprehension of the means and adaptation we at present possess for conveniently placing the patient during the operation of lithotomy, and for fixing and supporting the instruments. I think, in constructing this bed and the fixed support, I have been fortunate enough to improve that part of the science; and that these means may be fully appreciated, we will cast a *coup d'œil* on the advantages they possess.

Instead of the unsteady and disadvantageous position in which the patient is placed on a common bed, he is, on the rectangular bed, in the position most desired: all his limbs are semiflexed, the pelvis slightly elevated—his feet fixed in the slippers find a sufficient and convenient support, the trunk rests on an inclined plane, the head is raised, the arms free, the thighs naturally separated, leave the generative organs perfectly free, and, in fine, the unembar-

rassed position of the patient allows the surgeon to make with ease all the necessary movements. The operator is in an upright position, or nearly so, quite free, and consequently not at all fatigued, and can employ all the tact, delicacy, and gentleness of which he is master, in his movements, confident in the perfectness of his apparatus. Thus supported, he can take advantage of all the resources that present themselves for the destruction of the stone.

But if the bed has incontestible advantages as regards the ease of the patient and surgeon, the fixed support gives a certainty and promptitude to the operation which we cannot attain by the chevalet kept in place by the hand of an assistant.

Before the chevalet is grasped by the hand of the assistant, which is always necessary when these means are employed—before the instrument charged with the stone can be adjusted in the groove of the chevalet—the piece which contains the spiral spring, and which must press upon the perforator, can be connected with the extremity of the stem of this perforator—before the screw of this piece is fixed, and that of the spring unturned—the assistant taken his place to hold the instrument, and the surgeon passed the string of the bow round the pulley—before all this can be done the operator who employs the bed has had time to go on five or six times, and to have performed the drilling without any assistance. The manœuvres with the chevalet are long and embarrassing—those of the bed are quick, easy, and consequently favourable for the patient. This has been established by numerous comparative experiments, made both on stones out of the bladder, and on patients by the operation of lithotomy.

OBSERVATIONS

ON

M. BROUSSAIS' PRACTICE.

To the Editor of the London Medical Gazette.

SIR,

If the following observations should be deemed by you worthy of a place in your respectable publication, I shall

feel obliged by their insertion in your forthcoming number.

I am, Sir,

Your constant reader,

J. AARON, M.R.C.S.

Birmingham, Oct. 28th, 1829.

One of your contemporaries has recently given a case of "Gastro-enterocephalitis, so called, attended with malignant symptoms, successfully treated by M. Broussais, translated from the 10th vol. of the *Annals of Physiological Medicine*, for the perusal of the *British Physician*," and said to be "every way worthy of his serious consideration;" being "a most violent form of fever, attended with alarming symptoms, finally overcome by means so simple, and apparently so inefficacious, as to astonish the active practitioner." As I prefer a discussion on facts to an useless dispute about words, I shall not stay to consider the propriety of the name given to the disease in question; neither shall I enter into an examination of the doctrines advocated by M. B., as I do not profess to know much about them. I shall therefore content myself with commenting on the mode of treatment pursued in this particular case.

The disease occurred in a young man of "plethoric, robust, and well-constituted habit of body," after he had been for some days suffering from "derangement of the digestive function, attended with violent head-ache, aggravated no doubt by his constant application to study," and appeared to be induced by his having taken a walk in bad weather, while in this very susceptible state. He returned to his lodgings in the evening affected with fever, and on the next day had the usual symptoms of synocha, except that "diarrhoea" was present. In this state he was very properly bled (the report does not say to what amount!), and quietude, abstinence, and unstimulating drinks, enjoined. On the next day, the 28th of February, the report is, "same state as yesterday, only the pulse is less tense, the head-ache less violent." If this means any thing, it means that there was very little difference in the state of the patient from the preceding day, yet the bleeding was not repeated! Next report, "March 1st.—The whole abdomen painful on pressure; flatulency; borborygmi, with frequent liquid stools;

pulse more frequent, not so full, but harder; head-ache more violent, &c. An abundant epistaxis supervened during the night, which sensibly relieved him. Ten leeches to the anus!! Emollient fomentations to the abdomen; gum-water. 2d.—The night was calmer than yesterday; a slight remission of the symptoms." No treatment mentioned! "3d.—Aggravation of the inflammatory symptoms." No wonder. "Alvine discharges less frequent; tension of the abdomen; delirium during the night." Again no treatment mentioned!! Why was he not now bled, and why were not cathartics and diaphoretics exhibited?

"4th.—M. B. is called. Redness of tongue more circumscribed; appetite for cold drinks; epigastrium tumefied, tense, hot, and very painful; stools suppressed; urine scanty and high-coloured; and delirium at times furious; subsultus tendinum; pulse quick, small, and corded. Fifteen leeches to the epigastrium, five to each temple, and refrigerant applications to the head"—all for the first time! "Gum water.

"5th.—Tongue dry, very red towards the point, covered with a fuliginous coat, and the patient scarcely able to extend it beyond the lips; breath fetid; hypogastrium now tense and painful; borborygmi; discharges of fetid gas per anum; dysury; continuance of delirium, with loquacity alternating with muttering; carphology; subsultus tendinum; eyes haggard; hallucination, stupor, continual efforts to uncover the extremities; pulse small and quick;" and the only relief to this picture of the almost unchecked progress of the disease is a "sensible diminution of the pain and tenderness of the epigastrium!!" The pain and tension of the hypogastrium evidently arose from the suppression of the alvine discharges, yet no purgatives were administered! but "six leeches to the hypogastrium!!"—I suppose to draw away "the accumulated feces and refrigerants" to the head!!

"6th.—A very copious epistaxis came on about four in the morning, preceded by heat and redness of the face; the hæmorrhage continued to flow during the day and following night!" Now if this was not a most decisive proof of the previous necessity of much more active venesection, "then

am I a soused gurnet;" yet if further evidence be required by any one, what follows is surely sufficient to carry conviction to the mind of the most sceptical. "In consequence of this (*i. e.* the epistaxis) the patient gradually became more rational and collected; the countenance resumed its expression; the pulse rose, became fuller, and less frequent; the tongue moister, and the hypogastrium more supple." "Emollient cataplasms to the abdomen; continuation of refrigerants to the head." Still no cathartics!!

"7th.—Patient sensibly better; the tongue is less red, and its sooty coating has disappeared; abdomen supple; urine sufficiently abundant, free, and no longer high-coloured. He has had a copious alvine evacuation, very fetid, and as black as ink (he had swallowed a great quantity of blood); pulse less frequent, and hard; thirst very great. The arrival of the patient's relatives afforded him gratification, &c. Small enemata of cold water to be repeated two or three times in the day." This is the first time, be it observed, that any direct measures calculated to free the bowels were had recourse to!! "Refrigerants to the head.

"8th.—Prostration of strength, somnolency, intense thirst, desire for cold drinks (he asked for a piece of ice); abdomen has again become painful and tense; no alvine discharges; urine abundant; pulse again 100. Refrigerants to the abdomen; cold enemata!!

"9th.—Same state as last evening: same prescription!!

"10th.—Dryness of the throat; tongue fuliginous; greater tension of the hypogastrium; bowels continue costive; frequent desire to pass urine; slight cough; transitory delirium; continual somnolency; eyes turned convulsively upwards; subsultus tendinum." Can all this be wondered at, under such nugatory treatment? "Six leeches to the hypogastrium; emollient cataplasms to the abdomen instead of the refrigerants!"

But I will not trespass on your pages, nor the patience of your readers, by a regular detail and examination of the progress of the case, which is given at great length. Suffice it to say, that after a succession of slight amendments and severe relapses, which continued till the 10th of April, the patient "gained sufficient strength to leave his chamber

in a month afterwards!!!" This will not be surprising when it is observed, that the same want of energy as I have already noticed characterised the treatment throughout. Yet this case is held up by the *Lancet* as an example for the imitation of British physicians. It requires, I imagine, very little discrimination to perceive that the patient, in this case, owed his recovery (protracted as it was) much more to the strength of his constitution, than to the remedies employed; and as little, to be convinced that the great protraction of the disease was mainly attributable to the nugatory and trifling nature of the measures pursued. Yet, says your contemporary, "could we have the courage to follow, *pari passu*, the founder of the physiological medicine, and rely on similar means in the treatment of our fatal forms of fever, there is reason to believe that we should less frequently have to deplore the inefficacy of our art, and perhaps never the hurtful tendencies of our remedies!!" With the most perfect acquiescence in the latter part of the sentence I conclude, referring your readers to the case itself, and leaving them to form their own conclusions from the remarks made upon it by your contemporary.

EXTIRPATION OF AN ENLARGED OVARY.

To the Editor of the London Medical Gazette.

No. 19, Market-Street, New York,
October 11, 1829.

SIR,

KNOWING the deep interest you feel in every thing relating to the profession, I take the earliest opportunity of notifying you an operation which I have lately performed in this city for the removal of an enlarged ovarium—an operation great in magnitude and important in its results.

The subject of this case was a young woman from Ireland, aged 20 years, of a good constitution, and who had enjoyed good health until within two years. From that time to the present she has been tapped for ascites seven times, and the whole amount of fluid discharged by the several operations amounted to sixteen gallons. I performed the opera-

tion for the sixth time in July last. After the discharge of water I found the abdomen remained distended by a large tumor, occupying all the umbilical region, and extending into the pelvis on the left side. From the history of the case, I considered it an enlargement of the ovary, and suggested the possibility of removing it by an operation. She readily consented to this, and became anxious for its performance. On the 14th of September, after another tapping, and drawing off two gallons of a gelatinous fluid, I commenced the operation, by making an incision through the parietes of the abdomen, in the course of the linea alba, commencing two inches above the umbilicus, and carrying it to the pubes. The cyst of the tumor was firmly adherent to the peritoneum, for at least three inches in extent around the umbilicus. These adhesions, by a careful dissection, were all removed. The tumor was then drawn from the cavity of the abdomen, and the dissection continued in separating it from the broad ligament; this being done, the wound was immediately closed by stitches, and dressed with adhesive plaister. The solid part of the tumor, which was about one-third, weighed three pounds and a half. I was assisted in the operation by Professor Mott, Dr. Alex. Vaché, and my brother, Dr. J. H. Rogers.

It is now twenty-eight days since the operation, the wound has entirely healed, and as yet she has not had one unpleasant symptom.

When the result of this case shall be determined beyond all probability of doubt, I shall report it in detail in one of our periodical publications. The disease for which this operation was performed is very prevalent in this country, and since my return from England in June last, I have been consulted in several cases; and should this case prove successful, the removal of these tumors from the abdomen will become a common operation.

With much respect,

I remain your humble servant,
DAVID L. ROGERS.

AUSCULTATION.

To the Editor of the London Medical Gazette.

SIR,
It occurred to me the other day to wit-

ness the excellence of Mr. Painter's invention for deaf persons. I was both pleased and astonished at the extreme delicacy of the instrument, and it struck me that it might be advantageously applied to stethoscopic purposes. I accordingly made trial of it first upon the respiration of a child, by placing the ivory funnel a little below the clavicle, and the other extremity to my ear. The distance at which I sat from the subject of the experiment was about six feet—that is, the whole length of the tube; and I was gratified to find the respiratory movements conveyed to my ear with a distinctness which I had never experienced with the most approved wooden stethoscopes. The motions of the heart also were communicated with equal precision. Similar trials were then made on the adult, and with results no less satisfactory. These facts convince me that the acoustic tube is a better sound-conducting medium than the stethoscopes in ordinary use; and, by reason of its pliancy, many of the inconveniences attaching to the use of the solid cylinder may be completely obviated. Some of your readers, I trust, will be induced to avail themselves of these hints, by the due prosecution of which, I flatter myself, Mons. Laennec's admirable method of investigating a class of very obscure and yet important disorders, may receive still farther improvement.—I am, Sir,

Yours, &c.

F. BAILEY, M.D.

Reading, Nov. 12, 1829.

P.S.—I should recommend the patentees, Messrs. Painter and Co., surgeons, Warren-Street, Camden Town, to make the stethoscope about half the length of the acoustic instrument.

THE MEMBRANA TYMPANI.

To the Editor of the London Medical Gazette.

Sloane-Street, Nov. 2, 1829.

SIR,

If the following be considered worthy a place in your pages, it is at your service. Your obedient servant,

E. BOWDEN.

It has been long observed, that in the act of attentive listening the mouth is partially opened, which is believed to increase the power of hearing, and faci-

litate the transmission of feeble sounds to the internal ear through the Eustachian tubes. I believe the alteration in the form of the external auditory passage, which is produced by the opening of the mouth, has been overlooked; but, if I mistake not, it is to this cause any increased facility of hearing by such act is to be attributed. By placing the finger in the ear, and opening the mouth, the change in the form of the auditory passage is immediately observed, by the withdrawal of the articulating process of the lower jaw from within its axis, and thus enabling the sonorous undulations to impinge more directly upon the membrana tympani.

REMOVAL OF THE ARM, SCAPULA, AND CLAVICLE.

To the Editor of the London Medical Gazette.

SIR,

IN the last number of the Gazette, I have read with much interest a detailed account of the partial excision of the scapula, by Mr. Luke, of the London Hospital, on account of medullary sarcoma having taken root on a portion of that bone, and which appears to have been performed successfully, and in a masterly manner, by that gentleman.

I do not know whether the case be published, but in 1808, whilst doing duty at Greenwich Hospital, a young sailor, about 21 years of age, presented himself for a pension on account of the total removal, by operation, of the arm, scapula, and clavicle, and I perfectly remember our sending the man to the College of Surgeons, or to some one of the London hospitals, to be there examined as to the successful result of this formidable operation. Gun-shot wound, I think, was the injury inflicted, and the operation was determined on and performed by Dr. Ralph Cuming, then surgeon to the Naval Hospital at Antigua. Should you deem this notice of the case worthy of record, I beg you may insert it in your valuable journal.

Your's,

A. COPLAND HUTCHISON.

Duchess-Street, Portland-Place,
23d Nov. 1829.

MR. BATTLE'S PREPARATIONS.

To the Editors of the London Medical Gazette.

Maldstone, Nov. 16, 1829.

GENTLEMEN,

I HAVE been much disgusted with the account you have given of some preparations of opium, sarsaparilla, bark, &c. by Mr. Battley, whom you compliment as a respectable *chemist*. Are not all his preparations secret ones, or what are denominated *nostra*? If so, is it not inconsistent with the leading promise in your prospectus, to give them publicity? *

Mr. Battley, for about two years, continued to give, quarterly, an account of his analyses of opium, in the Medico-Chirurgical Review, by Dr. James Johnson, in each of which he promised to give an account of the mode of making his "sedative liquor of opium;" but after amusing the readers of that work for nearly two years, with statements in which I could not discover any thing like chemistry, the communications either ceased on his part or the learned Editor declined to give insertion to such plausible quackery; the object of which was to keep up the humbug of his sedative liquor. Now, gentlemen, to the point. Does this nostrum possess any advantage over liquid laudanum? I have tried it in numerous cases, in all of which, its effects have been exactly the same as I have always witnessed from opium. I have ascertained also, from analysis, that it contains, or at least affords on decomposition, morphine and narcotine: if so, what advantage can it have over opium? The fact is, it is a simple solution of opium in a dilute solution of pure *potass*, similar to that recommended by a French chemist (whose name I do not recollect, about fifteen years ago. If this assertion be not correct, Mr. Battley will of course deny it, in which case I will give you such evidence as in my opinion will establish its truth. With respect to his other *nostra*—viz. his preparations of Peruvian bark, sarsaparilla, and aloes, they are made in the same manner, and are like all articles of this class—*impositions*.

T. L., *Chirurgus*.

* Our correspondent is mistaken in this statement: we cannot give publicity to that of which we are ourselves ignorant; neither have we any recollection of puffing Mr. Battley or his *nostra* in this Journal.—ED. GAZ.

THE PHYSICIAN AND THE APOTHECARY.

To the Editor of the London Medical Gazette.

SIR,

At a time when the rapid advance of knowledge is proverbial, and every portion of science is, in the language of ephemeral cant, hastening to perfection, we may, with some advantage, be tempted to consider the present condition of our own profession. A former letter presented to your notice an endeavour to describe the general character of a good physician, and to define, as far as possible, the bounds of legitimate ambition, and the fairest mode of becoming useful to the world, as well as easy and contented in ourselves; and we may now descend to a more particular inquiry, and discriminately examine those two grades of the profession known by the titles of the physician and the apothecary; viewing them only under their individual relations, and comparing, without invidiousness, the essential differences only of their attainments and reputation. The progress of universal inquiry almost precedes the ancient veneration for dignities and honours; and the means of easy access to the various sciences and arts almost establishes an equality of knowledge. As far back as the middle of the last century, the physician might discreetly exert a dictatorial authority over the obsequious apothecary.—“Zounds!” said Dr. Norris, with mistaken indignation, “am I not a physician? Shall an apothecary dispute my nostrums? *Pharmacopola componat, medicus solus prescribat!*” (See the humorous Narrative of Dr. Norris, &c. &c. Swift’s Works.) That period has long past: the physician may advise, but he can now no longer exclusively direct the treatment of the sick; and the apothecary, or, in the language of the present day, the “general practitioner,” may, if he be properly educated, evince an ostensible equality with the physician, notwithstanding there exists a visible cause of depression both in public estimation and individual disqualification, which must still keep him in subjection. In what this inferiority of education and esteem consists, the following reflections may, at least, serve to suggest.

After a puerile education, a boy is removed at an early period from school, and placed under the careful superintendence of a medical practitioner; in whose shop he is to learn the nature of drugs, the prescribing of remedies, and the art and “mystery” of compounding medicines. Five years diligently spent in such employments, and in acquiring, perhaps, some manual dexterity, are usually deemed sufficient to qualify him for becoming a student and a scholar; and the youthful aspirant proceeds from the narrow limits of his master’s house to enter on a wider scene of action, and to commence the studious investigation of a profound and extensive science. With a mind regulated, perhaps, in its moral duties, but unprepared to comprehend and retain the weighty productions of learning, the demonstrations of hidden nature, and the probable conjectures of philosophic research, he advances in his pursuit with a wandering and obscure perception, and accumulates a strange and ill-assorted knowledge. The treasures of polite literature have yet to unfold their charms to him, nor can he reasonably be expected to assume the just pretensions of a gentleman, since he has been hitherto proudly excluded from the well-conducted circles of society. If his mind be vicious, and his appetites inclined to depravity, the favourable opportunity, or temptation rather, of self-independence, during the interval of an hospital education, exposes the means of sensual indulgence; and unrestrained by the open caution of friends, or the silent voice of classic instruction, he loses the ingenuous blush of modesty, and forgets the attendant shame of irregular conduct and small derelictions of principle. Medical studies are familiarized with filth, and an intimate acquaintance with disease and death may at first debase, before it elevates and ennobles the understanding, and fits it the more kindly for the observation and treatment of maladies. Without the power of extricating himself from the errors of his situation, he exercises with difficulty, or abuses, the means of acquiring information, precipitately risks the chance of a successful examination, and presents himself to the world less extensively educated and refined than the intelligent physician, but with a larger share of particular learning than the formerly useful apothecary. Superficial acquire-

ments are evanescent, finally leaving the mind more bare and uncouth than in a state of unenlightened simplicity: like gilding, which but feebly imitates the lustre of gold, and, when tarnished, is seldom the brighter from a second polish. With the confidence, without the peculiar spirit, of a scholar, the progress of self-improvement is terminated at the commencement of practical duties; after few years of diffuse application, the rigour of a public examination is presumed to be sufficient for the future guidance of a professional career; and the want of early mental cultivation impresses the unfruitful diligence of youth, and eventually stamps the unproductive character of the man. But a long and useful season of life has been wasted in the low employments of a shop: instead of the tedious term of apprenticeship, the fair endowments of a liberal education would supply the advantages of intellectual capacity and vigour of judgment; although it is the times, and not the false ambition of a few, that calls upon the apothecary to quit the narrow sphere of an honest and respectable inferiority. Yet let it not be imagined that the humble office of a medical apprentice is despicable, or that his time is misspent in the compounding of remedies, it being obvious, that, in a degree exactly proportioned to publicity of character and height of reputation, every station of life is in itself creditable, unless we forget to be honest and cease to be industrious. But the term of apprenticeship is, at the present day, unprofitable, because the public examination demands of the candidates an increased quantity of information; and, as it would be an anomaly in the history of scholastic tuition to seek from the student more learning than the course and opportunities of his education have permitted him to acquire, it might be profitable to discover, if possible, in what manner that demand may be frustrated, or become banefully efficient. If every class of medical practitioners be admitted into the profession through the medium of the same studies, the ancient title of apothecary subsides into a mere nominal distinction; and the "general practitioner" may issue from the schools of medicine of an equal value with the physician, if he be called upon to undergo equal examinations, to discharge

equal duties, and to risk an equal share of reputation: since similarity of knowledge implies similarity of power. This, however, is only theoretically true. The apothecary was, perhaps, a character formerly more really reputable than he is at present; since he has found the necessity of becoming more skilful, he has advanced from his station without a proportionate increase of authority, and often substitutes an apparent for the real possession of knowledge; although, when he is thoroughly educated, he is a man scarcely inferior to the physician himself.

At this novel conclusion we may arrive by the easy course of daily experience; and we may, with appropriate pity or admiration, find opportunities of observing, at our leisure, the presumptuous demands of ignorance, or the tacit advance of modest sense. But the physician must be superior to the apothecary, so long as he maintains the powerful ascendant of a classical education; for it is a truth universally admitted, that the diligent perusal of elegant literature not only inspirits and adorns the thinking mind, but is the only accurate mode of preparing it for scientific research and dignified conduct. In the practice of a liberal profession, the uncultivated understanding is always weak and impertinent. Besides the particular use and tendency of careful study, the delights of literature are wider and more various. The productions of good writers (such, at least, was the opinion of Cicero) may contribute to rouse the early slumbers of the morning, to animate the activity of noon, and to charm with pleasing reflections the silent privacy of night; under their influence solitude may be cheered, social manners polished, and the tedium of idleness gratefully beguiled; virtue may be established, and the powers of comprehension chastened and enlarged. He who would superciliously reject this warm eulogy of literature, by so high an authority, may be pronounced at once void of taste and feeling, and ignorant of the sweet solace of reading and retirement. The intelligent reader will complacently recognize the opinion of the sage Imlac—that "knowledge is certainly one of the means of happiness, as is confessed by the natural desire of every mind to increase its ideas. I am, therefore, inclined to conclude, that, if nothing counteract the natural

consequence of learning, we grow more happy as our minds take a wider range."

Here, then, we may pause, and remark that the essential difference between the physician and the apothecary lies, not in an unequal means of obtaining professional information, but in the different endowments of mental capacity. Some few, singularly blessed with intuitive genius, have become learned almost without instruction; but a greater number of adventurers, depraved and lost by too fondly relying on the unwieldy powers of genius, without the lively influence of polished tuition. Now, it would seem, is the appointed time for the "general practitioner" to advance himself; the path is open to public favour—the means are available of independent authority. Let it be remembered, that the character of a man's mind, during a single point or period of action, is often the character of his whole life. However varied may be the changes of fortune, individual identity is never destroyed; for the same mind, during health, will always evince the same kind of vigour under every condition—modified, indeed, by external circumstances, as well as by advancing years. Few can control or divert the onward tenor of manhood. Intelligence and uprightness of conduct are the beautiful products of early instruction; which, like all other beneficial qualifications, may be increased by perseverance and fortified by habit, embellished with erudition and illumined by peculiar talent, rendered useful by application, and amiable by benevolence of disposition. But mental dissipation, or the incontrollable loss of youthful vigour, can never be recovered; and, at a time of life when the mind is beginning to expand, the wasteful expenditure of five years is irretrievable; since every error, however small or insignificant, whether it arise from voluntary delinquency or unhappy compulsion, must invariably be productive of erroneous consequences and vexatious disappointment. Let the young student, therefore, carefully search into the depths of truth, and avail himself of the knowledge which the wisdom of former ages has delivered to us in books. The idler, and the man of pleasure, may smile with listless satisfaction at the cumbrous learning of the pedant, and rejoice that they themselves may

be, if they choose, more aptly fitted, without study, for the active duties of society: but it is the discriminative mark of a perverted mind to argue against the use, from the unskilful application, of any good thing, and wilfully to disregard that extensive benefit which the temperate exercise of solid information always diffuses. The possession of elegant learning is not incompatible with the duties of a medical man; and he, indeed, is placed under a deep responsibility, who would be an attendant on the sick without accurate research, and a familiar adviser without a well-regulated understanding. "Liberal arts and decent manners best adorn, or imitate, the inestimable gifts of genius and virtue."

MEDICULUS.

ANALYSES & NOTICES OF BOOKS.

"L'Auteur se tne à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

A Practical Treatise on Diseases of the Genitals of the Male; with a Preliminary Essay on the History, Nature, and General Treatment of Lues Venerea. By JOHN MADDOX TITLEY, M.D.

ALTHOUGH we possess some valuable monographs on individual diseases of the genital organs in the male, and an excellent comprehensive Treatise on Syphilis by Mr. Bacot, still the perusal of the publication before us has made us sensible that there was abundant room for a work which, embracing the various diseases of those parts, and giving to each its due share of notice and importance, should offer a correct, but succinct representation, of the present state of our knowledge as to their nature and treatment. Such, in our estimation, is the Treatise of Dr. Titley.

The work is divided into four parts—the first treating of *diseases of the penis*, the second of *diseases of the urethra*, the third of *diseases of the scrotum*, and the fourth of *diseases of the testicle, &c.* Under the head of diseases of the penis, we have—1. *diseases which originate from sexual intercourse*—the various forms of ulcer; 2. *buboes*; 3. *secondary venereal affections*—the various

Forms of eruption, iritis, and periostitis; 4. *diseases which may or may not originate from sexual intercourse*—as phimosis, paraphimosis, excoriation; and, 5. *diseases which do not originate from sexual intercourse*—as herpes, psoriasis, warts, tubercles, cancer, &c. Under diseases of the urethra, we have—1. *Gonorrhœa*—simple and venereal, chordee, gonorrhœal rheumatism, gonorrhœal ophthalmia, gleet; 2. *stricture of the urethra*—temporary and permanent, bleeding from the urethra, false passage, retention of urine from stricture, rupture of the urethra and extravasation of urine, fistulæ in perineo. Under diseases of the scrotum, we find *inflammation, suppuration, gangrene*—itching of the scrotum, chimney-sweepers' cancer, elephantiasis of the scrotum, &c. And under diseases of the testicle, &c. we have—chap. 1. *diseases of the tunics*, hydrocele, &c.; 2. *diseases of the spermatic cord*—circumcision, hydrocele of the cord; and, 3. *diseases of the testicle*—inflammation, fungus, hydatids, irritable testicle, neuralgia of the testicle, simple chronic enlargement, scrofulous enlargement, fungus hæmatodes, scirrhous, &c.

It is obviously impossible for us to attempt a detailed account of the manner in which the author has handled such a variety of subjects. We must be contented with stating generally, that it is marked by discrimination and judgment; that his descriptions of disease are correct, and the treatment recommended such as observation and experience have shewn to be the best. The style, too, has a character of vigour about it which does not allow the reader's attention to flag.

As a sample of the author's manner, we give one or two extracts:—

The Sloughing Ulcer.

“Although I have assigned a separate department to the consideration of sloughing ulcer, I wish distinctly to be understood that there is no particular kind of sore to which the term can be limited; but that every species of ulcer to which the genitals are liable, may, under certain circumstances, take on a gangrenous disposition. It is a knowledge of these circumstances which is essential to the successful treatment of cases, where, for the most part, extensive mutilation is to be dreaded.

“In considering the causes which are productive of gangrene of the penis, we must take a comprehensive view of the local and constitutional causes which lead to a similar result in other parts of the body. A fruitful source of mischief, and, indeed, I may justly say of misery, has arisen from the generally prevalent belief, that the sloughing of venereal ulcers is of a specific nature, and consequently that it is necessary to arrest it by a specific remedy. The first common principles of surgery have been forgotten under the delusive notion of contending with a specific disease. Hence has arisen the horrible practice of literally pouring in mercury in all cases where a venereal sore assumed a disposition to gangrene; it signified nothing whether the death of parts was the result of excessive or defective vascular action. Such was the treatment pursued at the principal hospitals in this metropolis, until within the last few years; and it is to be feared that this erroneous practice is still carried on by many who were pupils of these establishments, and who have not enjoyed the opportunity of witnessing the amended plan of treatment, which, it is consolatory to reflect, has been in most instances substituted.

“Ulcers of the genitals assume a sloughing disposition from local as well as general irritation, which gives rise to inflammation, and, ultimately, destruction of the parts. If we suppose the case of a healthy young man having a small sore on the penis, and at the same time using violent exercise on horseback, acute inflammation is set up in the diseased parts, and terminates in sloughing. Such then is gangrene, the result of excessive action, arising from local causes of irritation. On the other hand, a patient having a similar kind of ulcer may be excessively intemperate, so as to induce a feverish state of body, or he may be attacked with simple fever from common causes; the diseased part then partakes of the general increased vascular excitement, and, from local peculiarities, may go on to gangrene: this would be an instance of sloughing as the result of inflammation, arising from constitutional causes.

“The most dreadful cases of sloughing, however, are met with in a state of constitution diametrically opposed to that which I have just described. For

example, a man whose constitution is utterly enfeebled by intemperate habits, with whom there exists an absolute deficiency of vital power, both locally and generally, becomes infected with a venereal sore on the penis, which, in a man of healthy constitution, would readily yield to common means, but with him rapidly spreads, and the contiguous parts speedily become gangrenous. A similar condition of system may be engendered by a combination of circumstances operating upon a previously healthy habit; such as the profuse exhibition of mercury, and confinement in the crowded wards and tainted atmosphere of an hospital. It is scarcely necessary to say, that the two latter causes act upon a diseased habit with tenfold fury.

"After saying thus much of the pathology of sloughing venereal ulcers, it is unnecessary to enter into a minute detail of the requisite treatment, which here, as elsewhere, must be regulated by circumstances. I may briefly observe, that those cases which are obviously dependent upon increased vascular action, are most under control, as, by a judicious and early use of antiphlogistic means, it is in our power at once to arrest the progress of disease."

"Gonorrhæal Ophthalmia."

"It will not be considered irrelevant briefly to advert here to that most destructive form of ophthalmia which occasionally prevails during the progress of gonorrhœa, and which I believe to be in every instance produced by the direct application of the urethral discharge to the eye.

"The attack of this species of ophthalmia is generally very sudden: for the most part one eye only is affected, but occasionally the disease affects both, and there is then sometimes, though not generally, a diminution or suppression of the disease from the urethra. The seat of the disease, in the first instance, is in the membrana conjunctiva, which becomes red and swollen to a great degree, and with a rapidity which has no parallel in any other condition of this organ. The inflammation quickly extends to the cornea; a profuse purulent discharge takes place from within both the upper and lower palpebræ; the vessels of the transparent cornea become injected with red blood, and complete chemosis often ensues in forty-

eight hours, or even less. The rapidity with which the conjunctiva becomes engorged is sometimes truly astonishing, everting both the lids; and the discharge is profuse beyond what could be conceived, either from the space which affords it, or the time in which the disease runs its course. The pain attending it is extreme, and the symptoms of constitutional disturbance very severe. The inflammation extends into the interior of the eye, producing a sudden effusion of lymph into the anterior chamber, and ultimately ulceration or rupture of the cornea, and consequent destruction of the eye.

"It is obvious that in the treatment of these cases—where disease runs its course with such frightful rapidity—we must be proportionally active in our remedial means. Large blood-lettings, repeated according to circumstances, and the exhibition of tartrate of antimony, so as to induce and keep up nausea and faintness, are two of the most powerful agents in subduing inflammation. But my experience in the treatment of this disease leads me to prefer the exhibition of calomel in conjunction with the antimony; as, for instance, if we suppose an extreme case in which blood has been quickly abstracted to the amount of thirty, and I have sometimes bled even to forty ounces, I then commence with two grains of calomel and a quarter or a sixth of a grain of tartrate of antimony every hour or two.

"The pre-eminent value of calomel in arresting acute inflammation of *serous* membranes is so well known, and the remedy so generally had recourse to, that it would be superfluous to say any thing on that point; but I have always been of opinion that the importance of calomel in arresting acute inflammation of *mucous* membranes has not been sufficiently acted upon. If I should not be considered as entirely deviating from my subject, I would specially notice the utility of mercury in cases of acute inflammation of the lining membrane of the larynx, trachea, and bronchi.

"It must, however, be confessed, that in a great majority of cases, although from the beginning the disease may be treated in the most prompt and energetic manner, yet the means will prove insufficient.

"From a conviction of the insufficiency of the antiphlogistic treatment,

though pushed to the utmost extreme, in subduing this species of ophthalmia, a practice diametrically reverse in its nature has recently been adopted by several army surgeons. It consists in dropping into the eye a strong solution of nitrate of silver; ten, fifteen, or twenty grains to an ounce of distilled water. This practice is had recourse to in the commencement of the severest form of conjunctival ophthalmia; and it is said, that so far from producing, as might be supposed, any increase of pain, it is attended with the most decided advantages; the pain and redness of the membrane being overcome almost immediately, and the cure effected, even without the abstraction of blood. The testimonies in favour of this practice in conjunctival inflammation are, I must acknowledge, so satisfactory, that I should not hesitate to adopt it in gonorrhœal ophthalmia.

"There is a kind of chronic ophthalmia which occurs in conjunction with the rheumatic pains and swellings of the joints already described as occasionally taking place in the progress of gonorrhœa. This affection is very different from the formidable disease which I have just described. It appears that the conjunctiva, in common with the other mucous membranes of the body, is in a disordered condition; and it is worthy of remark, that in some instances this ophthalmic affection alternates with the pains in the limbs."

"Fungus of the Testicle."

"This disease is by no means of rare occurrence. Sometimes phlegmonous inflammation of the testicle terminates in a small abscess, which bursts, and from the ulcerated opening the fungus gradually protrudes. In other cases, a painful swelling of the testicle, particularly characterized by its hardness, is the first symptom of the disease. After an uncertain period of time, the integuments, growing gradually thinner, ulcerate; and after a slight discharge of matter, a firm and generally insensible fungus protrudes; the surrounding integuments are much thickened and indurated, so that there appears a considerable mass of disease; the pain abates, and the swelling subsides considerably after the integuments have given way. In this state the disorder appears very indolent; but if the fungus be destroyed by any means, the integuments come together, and a cicatrix is formed.

"The fungus has its origin in the glandular substance of the testis itself, the coats of which are destroyed to a certain extent, and a protrusion of the tubuli seminiferi takes place through the aperture. Sometimes, however, a fungous growth arises only from the tunica albuginea, the testicle itself being sound.

"In many instances the disease seems to be caused or accompanied by a morbid condition of the lining membrane of the urethra.

"The state of the testicle will serve to distinguish this disease from those fungi of a malignant character which frequently are situated on this part, and usually are the result of cancer or fungus hæmatodes of this organ, and wherein early extirpation is the only treatment which offers a chance of relief.

"It is to be remembered, in the treatment of this affection, that the fungus has no character of malignity attached to it, and consequently castration is never requisite, as regards the disease simply. With a view of bringing the case to a speedy termination, when the structure is so far destroyed that the discerning powers of the organ are lost, we may recommend complete extirpation; but in a majority of cases, by early attention, a milder treatment will suffice.

"When the disease has clearly originated in consequence of irritation communicated to the testicle by a morbid state of the urethra, the swelling will frequently subside, the fungus shrink, and a complete cure will be effected, on the removal of the cause by the means recommended in treating of disorders of the urinary passage. It is probable, indeed, that in other cases a cure might be accomplished by the unaided efforts of nature; the disease, however, is of so indolent a character that a spontaneous cure would prove a tedious process.

"The fungus may be removed with the knife, by ligature, or by escharotics; and likewise it may be got rid of by absorption under the use of pressure constantly applied. If the projection be large, it is perhaps the best practice to cut off the fungus, and having pared the hardened edges of the integuments, to bring them as closely in apposition as possible. The treatment by ligature is tedious. Of the escharotic applications, the nitrate of silver is preferable; it should be applied freely, dry lint should then be put over the part, and firm pressure made use of by the appli-

cation of adhesive plaister. Under the conjoined influence of the caustic, which effects the removal of the outer and less sensible part by sloughing, and the process of absorption excited by the pressure, the disease is more quickly removed than if either of the means were used singly. I have witnessed the application of a solution of arsenic in two instances: in one case very unpleasant symptoms arose from the absorption of this active poison, and in the other case there was less decided advantage than results from the lunar caustic, although no untoward constitutional derangement was produced.

"If after the removal of a fungus, the remaining portion of the testicle continue indurated and enlarged, it is advisable to have recourse to mercurial frictions, under the use of which, absorption of the interstitial deposit will take place."

The account of elephantiasis of the scrotum is particularly full, the author having had repeated opportunities of observing the disease in the West Indies, and where he operated on six patients by the removal of the diseased mass, all of whom recovered.

We may mention, that in the preliminary essay the author has endeavoured to shew "that no type of lues venerea now known can be proved or justly presumed to have been unknown in the earliest ages; historical evidence is against such a decision; and no symptomatic criterion between modern syphilis and various other venereal affections (followed by secondary symptoms) now known and included in the new plague of 1494—1496, has yet been demonstrated. And having moreover shown that mercury is in no sense a specific for any venereal disease, I maintain further, that lues is not a specific disease, inasmuch as its probable cause cannot be separated by any sure distinction from the cause of those affections described under the denomination of pseudo-syphilis, and which have been believed to be produced independent of sexual intercourse."

As the prostate is decidedly more a part of the genital than any other system, we are at a loss to account for its entire omission by our author; and when his work comes to a second edition, (which will probably be at no distant period,) we would recommend to him to supply this deficiency.

MEDICAL GAZETTE.

Saturday, Nov. 28, 1829.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."—CICERO.

REGULATIONS OF THE COLLEGE OF SURGEONS.

THE new code of regulations which has recently been issued by the Council of the London College of Surgeons, must be looked upon by every unprejudiced person as an improvement on those which they are intended to supersede. One of the most important changes relates to the attendance on provincial hospitals; a point, to the impolicy and injustice of which, as it stood in the late regulations, we have repeatedly directed attention.

On the last occasion of our adverting to the subject, we remarked, "the admission of some of the provincial towns to more equal terms is a demand so obviously just that we have no hesitation in saying, not only that they (the Council) ought to concede it, but that they must do so." A concession has accordingly been made. Four years' attendance on a provincial hospital was formerly required as equivalent to six months' corresponding attendance in London, Dublin, Edinburgh, Glasgow, or Aberdeen; whereas now the pupil is required to have attended only one year. But still a bone of contention is left, for with regard to the remaining six months, no period is admitted as an equivalent. As to the propriety of this regulation, there will probably be much difference of opinion; and as Uncle Toby very sagaciously remarks, "much may be said on both sides of the question." For ourselves we have no hesitation in stating that we regard the regulation as calculated to secure to the student better opportunities of learning his profession than he

would be likely otherwise to obtain ; and therefore it is fair to presume that the stock of knowledge which he lays in will be more extensive than if no such provision existed. Now if this be the test by which the measure is to be tried, we think there can be no doubt of its expediency. Neither have we any hesitation in affirming that the pupil who passes the first years of his professional studies in a provincial town, and comes to London with his mind already cultivated and prepared to receive every addition with avidity, will become a more accomplished surgeon than one whose education has begun and ended either in a provincial town or in the metropolis. One advantage, of no inconsiderable value, thus secured to him, will be that of attending the practice of two different hospitals. Any man who has seen much of our profession must have observed how apt the student is to pin his faith to the dicta of his teacher, adopting not only his opinions, but often his prejudices with them. If he settles in life at once, without an opportunity of witnessing the practice of others, his views remain permanently limited ; he sees only through the medium to which he has been accustomed ; or if he acquires a habit of seeing and thinking for himself, it is after a much longer period, and much more extensive experience. But if he attends in early life the practice and lectures of competent persons at different schools, he soon feels the necessity of judging for himself, and acquires a habit of referring to the book of nature as the only unerring authority by which the value of conflicting opinions can be duly estimated.

Were it left for the student to pursue what course his fancy might suggest ; were he told to acquire knowledge when and where he chose, without any defined curriculum, the standard of education would necessarily be lowered, and the door opened wide to the admission of a

crowd of persons from the lower classes of the community, who would be tempted, by the increased facilities and diminished expense, to enter a profession already over stocked. Every operative in Manchester would endeavour to make his son a *doctor* and a *gentleman*, till, in a few years, the unfortunate youth would envy the mechanical occupation of his father, and think that a village over-stocked with surgeons was worse than a market glutted with silks.

The outcry of the *levellers* (who, by the way, are now reduced to a few disappointed individuals, "the cankers of a calm world and a long peace,") is, that the meritorious part of the profession are starving ; and yet, with the same breath, they vociferate, down with all barriers—let merit be the only test—if merit met with its reward we should not be without practice, and our great champion would be at the head of his profession, instead of being restricted for a fortnight to a single patient—"a decent woman, lodging in Avery-Row." That distress does prevail in our profession, as well as in most other departments of the community, we cannot doubt. But while we admit this fact, and would willingly, in any reasonable manner, make our Journal instrumental to the relief of our suffering brethren, we must at the same time express our strong conviction that, in the great majority of cases, entire failure in practice is dependent upon incapacity or imprudence on the part of the individual ; and that they who now hunger after bread, are chiefly those persons who, in early life, never thirsted after knowledge. But from whatever cause the evil may arise, is it not a monstrous absurdity, with the fact of the profession being already too much crowded staring us in the face, to demand such changes in the system of education as would immediatel

render admission into it more easy, and success, when admitted, more difficult? In our opinion it ought, with all the corporate bodies, to be a fundamental principle to raise, rather than to depress, the standard of education; and every fair and rational means to accomplish the former object shall receive what assistance our humble support can afford it.

But to return. There is one rather amusing contradiction in the present regulations of the College of Surgeons, as to the period of study required; and which, if not a mere oversight, would seem to evince the very Quixotism of disinterestedness, instead of that abandoned devotion to Mammon which we are weekly assured the members of the council unanimously betray. It is, that candidates are required to bring proof "of having been engaged six years in the acquisition of professional knowledge." And again—

"Members and licentiates in surgery, of any legally constituted College of Surgeons in the united kingdom, and graduates in surgery of any university requiring residence to obtain degrees, will be admitted for examination on producing their diploma, license, or degree."

Now, as in other places four years is the minimum duration of study required, it is quite clear that the shortest route to Lincoln's-Inn Fields is by the way of Dublin, Glasgow, or Edinburgh. By this arrangement, too, the student, in his curriculum, need not so much as come within sight of any of those "human slaughterhouses," the London Hospitals, or any of the "Vampires" who live upon the blood of the patients. We marvel that our ingenuous contemporary has not expatiated on the great advantages to which this must give rise.

The greatest defects, however, in our opinion, as to these new regulations, are, first, that no order of succession in which the different branches of study

shall be followed, is enjoined; and, secondly, that the period of hospital attendance is so short. With regard to the former, it is indeed "recommended" that candidates shall have studied anatomy by attendance on lectures, and by dissections, during one season prior to attending the practice of an hospital: but of what use is it to "recommend," when the neglect of the recommendation carries with it no forfeit? If the advice be proper (which unquestionably it is), then ought it to have been made imperative, and not left optional. Anatomy, as we have elsewhere stated, is the very elements of surgery; and it is as necessary that a pupil should be master of it before he enters upon the study of surgery by lectures or hospital attendance, as that a boy should learn the Latin grammar before he attempts to construe. If, as many do, the pupil enter to his anatomy and hospital at the same time, such arrangement is injurious to both pursuits, and ruinous to the latter. He dissects till the latest moment—arrives at the hospital, perhaps, when the surgeon is already come, and contents himself with forming part of his "tail" for an hour, or perhaps but half that time; then hurries back to the anatomical lecture. And this leads us to remark, that the hours selected for teaching the different branches of medicine in London, are essentially bad. It would be much better that all the anatomical business should be completed before visiting the hospital. Full time should then be given for this; say from 12 to 2, or from 1 to 3, after which should come the lectures on disease, whether medical or surgical, while the mind of the student is fresh from its contemplation. Thus would the objects presented to him follow each other in natural succession, without that loss of time and jumble of ideas which result from the present system. According to the ex-

isting arrangements, the student probably opens the day with dissecting a little; but scarcely has he well begun when he is obliged to leave off, that he may attend his lectures on *materia medica* and the practice of medicine—his mind yet occupied with the *subject* he has just left. The lecture being ended, back he goes to dissect or to demonstration; after which he hurries to the hospital—returns to his anatomy—and has his surgery in the evening. A certain degree of variety is necessary to keep up attention, but changes so numerous and rapid as these cannot fail to confuse, and the alternation of ideas in the pupil's mind, could it be shewn on paper, would present the departments of science as arbitrarily, but not so distinctly depicted, as the intellectual organs in one of Mr. Deville's casts, or "the provinces in a map of revolutionary France."

SENTENCE IN THE CASE OF CLAPHAM.

THE sentence of the law has been pronounced against John Clapham, the unfortunate and misguided youth whom Wakley brought forward as a witness against Mr. B. Cooper. He has been condemned to six months' imprisonment in the common gaol. This is one of the fruits of that system of deception practised upon the young and inexperienced, by which they are led to the belief, that the various Corporate Institutions of this country are illegal; because it suits the interested purpose of a flagitious journalist to call them so. This belief once adopted, the next step is easy. "If they be not lawful," say these sophists, "it cannot be unlawful to overreach them;" and thus do they commit those misdemeanors which are visited with such serious and disgraceful punishment—punishment which not only interferes with a young man's prospects for the time, but which

fixes a brand of infamy upon his brow which can never be effaced. We are the more anxious to insist upon this point, because we know that a large number of cases have lately occurred, in which attempts have been made to practise various deceptions upon the Society of Apothecaries. We beseech those who would avoid getting into trouble, if actuated by no better motive—to take warning by the case we now record.

"Mr. Justice BAYLEY, after the Judges had conferred together for a few minutes, addressed the defendant, and said that no man with proper feelings of morality, or proper feelings of integrity, could fail to shrink from the means which the defendant had adopted to procure his license from the Apothecaries' Company. The question was not one of fitness or unfitness in any particular individual to practise as an apothecary. The legislature had determined that no man should practise unless he had passed a regular examination before the Court of Examiners of the Apothecaries' Company, and that that Company should not be at liberty to grant a license to any person who should be under the age of 21 years. It had been represented by the affidavits that the defendant's father bore a most unexceptionable character, and that the character of the defendant himself, with this single exception, was also unimpeachable; but this was a most momentous exception; for no man of right feelings would ever have ventured to do that which the defendant had done. The sentence of the court was, that he be imprisoned in the gaol at Huntingdon for the county of Huntingdon, for the space of six calendar months, and in the meantime be committed to the custody of the Marshal of the Marshalsea."—*Times*, Nov. 20.

MR. EARLE'S LETTER.

MR. EARLE's letter, published in our last number, has excited a considerable sensation in more quarters than one. The manner in which the subject has been viewed by the gentlemen attending his Clinical Lectures must be as gra-

tifying to his feelings as it is creditable to theirs. Nothing could exceed the cordiality (we might say enthusiasm) with which they received him last Saturday evening.

By the way, can any of our readers guess for what purpose the "copy" was suddenly sent for from the printing office of Messrs. Mills, Jowett, and Mills, when it was already in the hands of the compositor; or who the gentleman was that called in Bedford-Square, at three o'clock on Tuesday the 17th instant, being the day after Mr. Earle's letter was sent to Wakley?

VACCINATION.

THE following appears to us to contain the most *convincing* argument in favour of vaccination which we have yet met with:—

"**SMALL POX.**—Information having been given that this dangerous and infectious disease is very prevalent in various parts of this city, public notice has been issued, by order of a court of mayoralty, recommending to the inhabitants immediately to have recourse to vaccination, and stating that the poor inhabitants may receive from the Corporation of Guardians a reward of two shillings and sixpence for each person who may be vaccinated."—*Bury and Norwich Post*, Nov. 18.

SIAMESE BOYS.

WE had an opportunity of examining these boys at a "private inspection," last Tuesday. We have little to add to the account which we published in the *Gazette* of October 31.

The boys are said to be eighteen years of age: they are rather short; bear the same close resemblance to each other that twins usually do; and both are slightly marked with small pox. They are two perfectly distinct individuals, but connected by a cartilaginous band passing from the lower part of the sternum in

one, to a corresponding point in the other; at the inferior part of this bond of union is *one* umbilicus. Their actions are consentaneous, just as those of any two persons might be supposed to become if they were artificially bound together. There is not a vestige of room for supposing that there is moral connexion between them more close than this. When we published the account forwarded to us by Dr. Ashburner, we conjectured that the boys might be separated by an operation: after having seen them, we still regard this as possible, though its expediency or perfect safety under present circumstances might be matter of question. It is stated, by M. Mayor, in the *Journal de Geneve*, for July 30, 1829, that two girls, united in a similar manner—the union extending from the sternum to the umbilicus—were separated by an operation, and that they both lived.

The boys are very intelligent and observing, various illustrations of which are given by the persons about them. When in America, a gas-chandelier instantly caught the attention of both, which they remarked as "a light without oil or tallow." The steam-engine completely puzzled them; they sat for hours contemplating it, wholly at a loss to account for the power which moved it, till at length the steam being turned off, they seemed at once to perceive that in it the force resided which communicated motion, and from this time their wonder was at an end. Neither do they seem destitute of humour—indeed their countenances express a good deal, and they seem to be much amused with many things passing around them. At Philadelphia, the charge for seeing them was half a dollar, and a gentleman who had lost an eye having come in, one of them remarked that he hoped they had only made him pay a quarter of a dollar, as he had but half the means of seeing them that other people had.

HOSPITAL REPORTS.

GUY'S HOSPITAL.

Bite of a Cat.

JOHN HICKS, æt. 24, a sailor, accustomed to free libations, was admitted into Accident Ward, Nov. 2d, 1829, under the care of Mr. Key. He stated that two days since, observing a cat "in fits," he endeavoured to drive it away; but his manœuvres failing, he seized her by the neck, and threw her away, since which he has not seen the cat. However, she in return bit him twice, and retained her teeth in the left thumb, about the joint, for some time. Pain in the thumb and arm came on within twenty-four hours, for which he thought spirits a proper remedy. He had no sleep last night, and is now in a state of excitement. Pulse 110, full and jerking; tongue loaded, and rather dry; heat of skin above the ordinary temperature. Pain in the head, and in the injured thumb and arm, in the latter of which there is an inflammatory blush, extending to the elbow, in the course of the absorbents.

V. S. ad 3xvj. st. Colocynth c. Cal. grs. xx. st. et Opii. gr. j. nocte, si opus fuerit.

Nitrate of silver was freely rubbed on the inflamed parts of the fore-arm, to produce vesication, and a linseed-meal poultice enveloped the hand, the bites being filled with pure liq. ammoniæ.

3d.—His pulse is considerably lowered in force and frequency by the venesection; he has slept well by the aid of the opium pill; and his bowels have been duly acted upon, though not till some house medicine was given. He has no headache; tongue cleaner, and skin moist; the pain in his arm is also decidedly relieved; nor have the inflammatory lines extended since yesterday.

5th.—Yesterday he was altogether better; but to-day his thumb is much swollen, and painfully throbbing. He did not sleep well last night; pulse quick and frequent, tongue furred.

Cap. statim Colocynth c. Calom. gr. xv.

6th.—The purgative pills have acted copiously; he slept better last night. Pulse 88, full, and not readily compressible; tongue much cleaner, and skin moist. He has now neither inflammation, (except the vesication produced by the caustic), nor pain in the arm, and only slight lancinating pains in the thumb. A little pus was evacuated from the site of an old scar, just over the metacarpo-phalangeal joint of the thumb.

9th.—His bowels have required the occasional exhibition of aperient medicine, but his thumb is greatly improved in appearance.

17th.—On moving the joint where the bites were, there is a sense of grating communicated.

23d.—The bites are quite healed, but there appears to be such relaxation of the

lateral ligaments as to produce unnatural grating motion when the joint is curved laterally.

Chronic inflammation and disorganization of the Foot—Amputation.

W. T. æt. 40, was attacked by inflammatory œdema of his right leg about fifteen years ago, which soon subsided under properly applied pressure and rest. A few years after that period he struck his shin, and produced an indolent sore, which, from inattention, became surrounded by considerable cellular inflammation. This inflammation of the cellular web of the foot has never since entirely subsided; and from repeated attacks of adhesive and ulcerative inflammation, his foot has become enormously enlarged, so much so as, on superficial inspection, to resemble elephantiasis. Not only is there extreme induration of the cellular web of the foot, but from its great size, when compared with its fellow, the bones are probably enlarged, there being perhaps some absorption of the phosphate of lime, and a copious deposition of strumous fatty matter, whence the tarsal bones are greatly enlarged and softened. His countenance is pale, perhaps somewhat œdematous. Pulse 120, quick, but compressible. Bowels rather costive, tongue white, and furred.

R Extr. Coloc. c. Calom. gr. x. et Ol. Ricini, 3vj. postea Folus Lini Cruri.

Notwithstanding some slight improvement in the leg, the man submitted to Mr. Key's advice to have the cumbersome member removed. On Tuesday, October 27th, therefore, it was removed in the usual circular mode of amputation, below the knee. Five arteries required to be tied, and it was a long time before the oozing of blood from the stump was so inconsiderable as to warrant his removal from the theatre. The stump was not dressed till two hours after the amputation.

He took two grains of calomel and one grain of opium at night. Some oozing of serous blood continued for about thirty hours afterwards; spasmodic action of the muscles was frequent and severe; but the man continued pretty well till the fourth day, when his stump became tense and painful, and febrile symptoms shewed themselves.

R Ex. Coloc. gr. xij. Calom. gr. iij. st. et postea Haust. Sennæ.

The straps of plaister were snipped, and some sanious matter discharged; and, instead of a cold damp pledget of lint, a bread poultice was applied warm.

5th day.—There is less febrile excitement about him to-day than since the operation, and he slept well last night. The adhesive straps were further divided, and a considerable quantity of bloody pus allowed free exit. The lips of the wound looked free from in-

inflammation where granulating, and at the upper and lower parts were pretty firmly adherent. One of the ligatures was removed to-day, and the others have come away since.

Nov. 10th, (14th day).—He has been progressing well till this morning, when he had a rigor, which was followed by feverishness. There is pain on pressing the right hypogastric region, extending to the loins. His tongue is much furred, and his pulse frequent and quick, though evidently without power; skin hot: the stump looks well.

App. Hirudines, xx. reg. hypogast. Cos. Potus Cruri.

15th day.—There is still some tenderness, increased by pressure. Tongue dry, and darker in colour; bowels have not been opened since yesterday; pulse 128, and quick; respiration more frequent. He has not had any repetition of the rigors.

R Hydr. c. Crota, gr ij. Ext. Conii, gr ij. Pul. Ipec. gr j. in forma Pil. tertius horis cap.

16th day.—He has not slept much during the past night, but considers himself rather better, pulse 128, very compressible, but quick; skin hot; tongue much browner, and moist. The pain in the right epigastrium has subsided, but there is a diffused tenderness over the abdomen. His right lung appears to be now the chief seat of inflammatory action; respiration 50 per minute, and irregular; sound somewhat dull on the right side, about the middle lobe of which lung crepitating rattle may be occasionally heard; he appears rather exhausted.

App. Cucurb. Cruentæ et detrahentæ Sanguinis e. later. dextr. 3vj.

After the cupping his pulse fell to 110, and his pain in respiration was decidedly relieved; but in an hour afterwards the pulse rose in frequency.

17th day.—He has slept better, being more free from pain, which is now confined to the epigastrium; his respiration is less frequent, crepitating rattle not so perceptible, and he breathes with more freedom; expectoration viscid and copious; bowels open; tongue dry and brown; gums are a little sore; pulse 125, quick, but fuller; the stump has not granulated soundly; there are hollows above and below the central of adhesion.

18th day (18th).—He can inspire with pain; has slept well; skin cool; soft, 116, and less quick; tongue red and less brown.

Since the above date he has continued to improve, and is now (Nov. 20th) without any unfavourable symptom.

Excision of a large Portion of the Lower Jaw.
On Tuesday, November 17th, Mr. J.

excised nearly half of the lower jaw of an elderly man, on account of fungoid exostosis. It appeared that he had suffered much from a decayed tooth several months ago, and that, some time after this, swelling of the alveolar processes occurred; which has, within the last two months, increased so rapidly as to thrust out, or render carious, the other teeth on the same side. The man is in good health, and the tumor not very large. Mr. M. amputated the jaw from the symphysis to the ramus. The operation, necessarily tedious, lasted about forty minutes. Not a single bad symptom has appeared since the operation, and at the first dressing much of the wound was adherent.

WESTMINSTER HOSPITAL.

Fractured Sternum and Ulna.

JOHN CLARK, admitted Nov. 26, 1829. States that he was riding, when his horse ran away with him, and came in contact with a cart. He was thrown, and the horse fell upon his body. When he was admitted, he was blanched and breathing with great difficulty. Pulse extremely small, and countenance very anxious. Pupils slightly dilated, and eyes vacant in expression.

On examining him after he was put to bed, a deep depression was observed, about an inch and a half from the lower extremity of the sternum, and the edges of two of the ribs immediately beyond the cartilage were felt projecting beyond their level. The sternum was fractured across the lower portion: the lower edge stood out more than natural, while superiorly—that is to say, at the line of fracture—it was strongly indented, like a half broken stick bent so far as to form an angle. The slightest pressure on the fractured points was attended with great pain. The ulna was also fractured about the middle. He seemed every where else to have escaped injury.

Two hours after the first examination.—His pulse has risen, being more frequent and less feeble; his breathing is not quite so difficult, but he complains of excruciating pain at the seat of the fracture.

Nov. 7th.—He was bled yesterday evening to 3vj. and ordered the following

The roller has been reapplied. The arm is considerably swelled.

Nov. 9th.—He is better to-day.

Haust. Cathart.

Nov. 11th.—He suffers but little inconvenience. His arm has been put up in splints, and he is moving about.

Nov. 15th.—He has merely a slight pain across the chest when he draws in a full breath. His arm is easy.

Nov. 18th.—He says he now suffers no inconvenience whatever from the accident, except the not being able to use his arm.

This case is remarkable from the very rapid manner in which the symptoms of the injury disappeared; and altogether the trifling inconvenience he suffered from the accident, which, on his admission, appeared of a serious nature.

Inflammation of the Hand.

Sarah Broadhurst, æt. 50, admitted Oct. 21st, under the care of Mr. Lynn. This patient had been attending as an out-patient for several weeks, with a diseased hand—one of those cases where inflammation attacks a part without any evident cause—going on to suppuration, and destroying ligaments, bones, &c.

About eight weeks ago, she was seized with a pain in her right side, and two days after it seemed to shoot across her body and fix in her hand. In the course of a couple of days it had swelled; the skin was distended and black; she felt it hot, and excessively painful. The hand and arm was fomented, and she was afterwards bled. It was fomented for a fortnight, and then poulticed for a week. During this time it remained much the same; greatly swelled, and very painful. She cannot attribute it to any cause, except that she fell down, about two years ago, and hurt her elbow, never having been able to lean upon it since.

She has been married upwards of thirty years, and had nine children: the last was born fourteen years ago. She began to menstruate about the age of seventeen, and ceased six years ago. She has always enjoyed remarkably good health, been excessively strong, and free from pain of every kind.

Oct. 25.—The hand and wrist is at present red, swelled, and stiff. She complains of great pain, particularly at night. On moving the wrist, the bones of the carpus may be heard to "clink" against each other. She has no pain except in the diseased part. Bowels open; tongue clean; pulse rather weak, otherwise natural. Fomentations to the part.

Oct. 29th.—There is scarcely any alteration in the hand.

Nov. 4th.—The hand has been improving considerably. There is less heat and pain.

She has been kept perfectly quiet. She has determined on going out to-day, on account of her husband's illness.

CHELTENHAM CASUALTY HOSPITAL.

Severe Case of Vomiting attending Pregnancy.
Treated by Dr. CHRISTIE.

ELIZABETH JOHNSON, æt. 23, admitted a patient August 2, 1828; she was seized yesterday with violent vomiting and pain in the bowels, which lasted nearly the whole of the day without intermission, but she did not apply for relief till this morning early. She then complained of pain in the epigastrium (which was relieved by pressure), and continued vomiting (of a brown colour). She appeared to be very much exhausted, and laboured under great prostration of strength. Her bowels had not been opened for three days. Urine of a natural colour; pulse rather small, and beat about 80; tongue loaded with a whitish fur; body cold, and covered with perspiration. She is about two months gone with child.

Ordered Mist. Effervescens. c. Liq. Opii Sedat. Pil. Calomel. Ext. Col. c. et Ol. Croton.

3d.—Vomiting and pain in the stomach unabated; pulse as yesterday; bowels hard; no tenderness on pressure.

Applic. Emplast. Cantharid. Regioni Epigast. Contin. Pil. et Mist. Efferves. Ordered to have large enemata.

4th.—The vomiting has not ceased for more than an hour throughout, except yesterday, when, after the blister was dressed, she thought it was nearly two hours before it returned, but it then came on with increased violence. Repeat enemata.

R Hydrarg. Sub. gr. xij. Pil. Saponis c. Opio, gr. xvij. Ol. Cinnamon. mjj. Fiat Pil. vi. Capiat, j. tertius hora.

5th.—Vomiting rather worse, and the fluid which is thrown up is about the colour of tea. Pulse rather full, and quicker than yesterday; bowels open; slight pain on pressure; tongue cleaner on the sides, and red.

Fiat V. S. ad 3xvi. R Aquæ Cinnamon, 3ij. Tinct. Opii, 3i. m. Capiat, 3ss, omni tertia hori.

6th.—Stomach still as irritable as yesterday, and rejects every thing taken. Pulse not so full, but she complains of great pain in the epigastric region, increased by pressure.

example, a man whose constitution is utterly enfeebled by intemperate habits, with whom there exists an absolute deficiency of vital power, both locally and generally, becomes infected with a venereal sore on the penis, which, in a man of healthy constitution, would readily yield to common means, but with him rapidly spreads, and the contiguous parts speedily become gangrenous. A similar condition of system may be engendered by a combination of circumstances operating upon a previously healthy habit; such as the profuse exhibition of mercury, and confinement in the crowded wards and tainted atmosphere of an hospital. It is scarcely necessary to say, that the two latter causes act upon a diseased habit with tenfold fury.

"After saying thus much of the pathology of sloughing venereal ulcers, it is unnecessary to enter into a minute detail of the requisite treatment, which here, as elsewhere, must be regulated by circumstances. I may briefly observe, that those cases which are obviously dependent upon increased vascular action, are most under control, as, by a judicious and early use of antiphlogistic means, it is in our power at once to arrest the progress of disease."

"Gonorrhœal Ophthalmia."

"It will not be considered irrelevant briefly to advert here to that most destructive form of ophthalmia which occasionally prevails during the progress of gonorrhœa, and which I believe to be in every instance produced by the direct application of the urethral discharge to the eye.

"The attack of this species of ophthalmia is generally very sudden: for the most part one eye only is affected, but occasionally the disease affects both, and there is then sometimes, though not generally, a diminution or suppression of the disease from the urethra. The seat of the disease, in the first instance, is in the membrana conjunctiva, which becomes red and swollen to a great degree, and with a rapidity which has no parallel in any other condition of this organ. The inflammation quickly extends to the cornea; a profuse purulent discharge takes place from within both the upper and lower palpebræ; the vessels of the transparent cornea become injected with red blood, and complete chemosis often ensues in forty-

eight hours, or even less. The rapidity with which the conjunctiva becomes engorged is sometimes truly astonishing, everting both the lids; and the discharge is profuse beyond what could be conceived, either from the space which affords it, or the time in which the disease runs its course. The pain attending it is extreme, and the symptoms of constitutional disturbance very severe. The inflammation extends into the interior of the eye, producing a sudden effusion of lymph into the anterior chamber, and ultimately ulceration or rupture of the cornea, and consequent destruction of the eye.

"It is obvious that in the treatment of these cases—where disease runs its course with such frightful rapidity—we must be proportionally active in our remedial means. Large blood-lettings, repeated according to circumstances, and the exhibition of tartrate of antimony, so as to induce and keep up nausea and faintness, are two of the most powerful agents in subduing inflammation. But my experience in the treatment of this disease leads me to prefer the exhibition of calomel in conjunction with the antimony; as, for instance, if we suppose an extreme case in which blood has been quickly abstracted to the amount of thirty, and I have sometimes bled even to forty ounces, I then commence with two grains of calomel and a quarter or a sixth of a grain of tartrate of antimony every hour or two.

"The pre-eminent value of calomel in arresting acute inflammation of *serous* membranes is so well known, and the remedy so generally had recourse to, that it would be superfluous to say any thing on that point; but I have always been of opinion that the importance of calomel in arresting acute inflammation of *mucous* membranes has not been sufficiently acted upon. If I should not be considered as entirely deviating from my subject, I would specially notice the utility of mercury in cases of acute inflammation of the lining membrane of the larynx, trachea, and bronchi.

"It must, however, be confessed, that in a great majority of cases, although from the beginning the disease may be treated in the most prompt and energetic manner, yet the means will prove insufficient.

"From a conviction of the insufficiency of the antiphlogistic treatment,

though pushed to the utmost extreme, in subduing this species of ophthalmia, a practice diametrically reverse in its nature has recently been adopted by several army surgeons. It consists in dropping into the eye a strong solution of nitrate of silver; ten, fifteen, or twenty grains to an ounce of distilled water. This practice is had recourse to in the commencement of the severest form of conjunctival ophthalmia; and it is said, that so far from producing, as might be supposed, any increase of pain, it is attended with the most decided advantages; the pain and redness of the membrane being overcome almost immediately, and the cure effected, even without the abstraction of blood. The testimonies in favour of this practice in conjunctival inflammation are, I must acknowledge, so satisfactory, that I should not hesitate to adopt it in gonorrhœal ophthalmia.

"There is a kind of chronic ophthalmia which occurs in conjunction with the rheumatic pains and swellings of the joints already described as occasionally taking place in the progress of gonorrhœa. This affection is very different from the formidable disease which I have just described. It appears that the conjunctiva, in common with the other mucous membranes of the body, is in a disordered condition; and it is worthy of remark, that in some instances this ophthalmic affection alternates with the pains in the limbs."

"Fungus of the Testicle."

"This disease is by no means of rare occurrence. Sometimes phlegmonous inflammation of the testicle terminates in a small abscess, which bursts, and from the ulcerated opening the fungus gradually protrudes. In other cases, a painful swelling of the testicle, particularly characterized by its hardness, is the first symptom of the disease. After an uncertain period of time, the integuments, growing gradually thinner, ulcerate; and after a slight discharge of matter, a firm and generally insensible fungus protrudes; the surrounding integuments are much thickened and indurated, so that there appears a considerable mass of disease; the pain abates, and the swelling subsides considerably after the integuments have given way. In this state the disorder appears very indolent; but if the fungus be destroyed by any means, the integuments come together, and a cicatrix is formed.

"The fungus has its origin in the glandular substance of the testis itself, the coats of which are destroyed to a certain extent, and a protrusion of the tubuli seminiferi takes place through the aperture. Sometimes, however, a fungous growth arises only from the tunica albuginea, the testicle itself being sound.

"In many instances the disease seems to be caused or accompanied by a morbid condition of the lining membrane of the urethra.

"The state of the testicle will serve to distinguish this disease from those fungi of a malignant character which frequently are situated on this part, and usually are the result of cancer or fungus hæmatodes of this organ, and wherein early extirpation is the only treatment which offers a chance of relief.

"It is to be remembered, in the treatment of this affection, that the fungus has no character of malignity attached to it, and consequently castration is never requisite, as regards the disease simply. With a view of bringing the case to a speedy termination, when the structure is so far destroyed that the discerning powers of the organ are lost, we may recommend complete extirpation; but in a majority of cases, by early attention, a milder treatment will suffice.

"When the disease has clearly originated in consequence of irritation communicated to the testicle by a morbid state of the urethra, the swelling will frequently subside, the fungus shrink, and a complete cure will be effected, on the removal of the cause by the means recommended in treating of disorders of the urinary passage. It is probable, indeed, that in other cases a cure might be accomplished by the unaided efforts of nature; the disease, however, is of so indolent a character that a spontaneous cure would prove a tedious process.

"The fungus may be removed with the knife, by ligature, or by escharotics; and likewise it may be got rid of by absorption under the use of pressure constantly applied. If the projection be large, it is perhaps the best practice to cut off the fungus, and having pared the hardened edges of the integuments, to bring them as closely in apposition as possible. The treatment by ligature is tedious. Of the escharotic applications, the nitrate of silver is preferable; it should be applied freely, dry lint should then be put over the part, and firm pressure made use of by the appli-

cation of adhesive plaister. Under the conjoined influence of the caustic, which effects the removal of the outer and less sensible part by sloughing, and the process of absorption excited by the pressure, the disease is more quickly removed than if either of the means were used singly. I have witnessed the application of a solution of arsenic in two instances: in one case very unpleasant symptoms arose from the absorption of this active poison, and in the other case there was less decided advantage than results from the lunar caustic, although no untoward constitutional derangement was produced.

"If after the removal of a fungus, the remaining portion of the testicle continue indurated and enlarged, it is advisable to have recourse to mercurial frictions, under the use of which, absorption of the interstitial deposit will take place."

The account of elephantiasis of the scrotum is particularly full, the author having had repeated opportunities of observing the disease in the West Indies, and where he operated on six patients by the removal of the diseased mass, all of whom recovered.

We may mention, that in the preliminary essay the author has endeavoured to shew "that no type of lues venerea now known can be proved or justly presumed to have been unknown in the earliest ages; historical evidence is against such a decision; and no symptomatic criterion between modern syphilis and various other venereal affections (followed by secondary symptoms) now known and included in the new plague of 1494—1496, has yet been demonstrated. And having moreover shown that mercury is in no sense a specific for any venereal disease, I maintain further, that lues is not a specific disease, inasmuch as its probable cause cannot be separated by any sure distinction from the cause of those affections described under the denomination of pseudo-syphilis, and which have been believed to be produced independent of sexual intercourse."

As the prostate is decidedly more a part of the genital than any other system, we are at a loss to account for its entire omission by our author; and when his work comes to a second edition, (which will probably be at no distant period,) we would recommend to him to supply this deficiency.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."—CICERO.

REGULATIONS OF THE COLLEGE OF SURGEONS.

THE new code of regulations which has recently been issued by the Council of the London College of Surgeons, must be looked upon by every unprejudiced person as an improvement on those which they are intended to supersede. One of the most important changes relates to the attendance on provincial hospitals; a point, to the impolicy and injustice of which, as it stood in the late regulations, we have repeatedly directed attention.

On the last occasion of our adverting to the subject, we remarked, "the admission of some of the provincial towns to more equal terms is a demand so obviously just that we have no hesitation in saying, not only that they (the Council) ought to concede it, but that they must do so." A concession has accordingly been made. Four years' attendance on a provincial hospital was formerly required as equivalent to six months' corresponding attendance in London, Dublin, Edinburgh, Glasgow, or Aberdeen; whereas now the pupil is required to have attended only one year. But still a bone of contention is left, for with regard to the remaining six months, no period is admitted as an equivalent. As to the propriety of this regulation, there will probably be much difference of opinion; and as Uncle Toby very sagaciously remarks, "much may be said on both sides of the question." For ourselves we have no hesitation in stating that we regard the regulation as calculated to secure to the student better opportunities of learning his profession than he

would be likely otherwise to obtain ; and therefore it is fair to presume that the stock of knowledge which he lays in will be more extensive than if no such provision existed. Now if this be the test by which the measure is to be tried, we think there can be no doubt of its expediency. Neither have we any hesitation in affirming that the pupil who passes the first years of his professional studies in a provincial town, and comes to London with his mind already cultivated and prepared to receive every addition with avidity, will become a more accomplished surgeon than one whose education has begun and ended either in a provincial town or in the metropolis. One advantage, of no inconsiderable value, thus secured to him, will be that of attending the practice of two different hospitals. Any man who has seen much of our profession must have observed how apt the student is to pin his faith to the dicta of his teacher, adopting not only his opinions, but often his prejudices with them. If he settles in life at once, without an opportunity of witnessing the practice of others, his views remain permanently limited ; he sees only through the medium to which he has been accustomed ; or if he acquires a habit of seeing and thinking for himself, it is after a much longer period, and much more extensive experience. But if he attends in early life the practice and lectures of competent persons at different schools, he soon feels the necessity of judging for himself, and acquires a habit of referring to the book of nature as the only unerring authority by which the value of conflicting opinions can be duly estimated.

Were it left for the student to pursue what course his fancy might suggest ; were he told to acquire knowledge when and where he chose, without any defined curriculum, the standard of education would necessarily be lowered, and the door opened wide to the admission of a

crowd of persons from the lower classes of the community, who would be tempted, by the increased facilities and diminished expense, to enter a profession already over stocked. Every operative in Manchester would endeavour to make his son a *doctor* and a *gentleman*, till, in a few years, the unfortunate youth would envy the mechanical occupation of his father, and think that a village over-stocked with surgeons was worse than a market glutted with silks.

The outcry of the *levellers* (who, by the way, are now reduced to a few disappointed individuals, "the cankers of a calm world and a long peace,") is, that the meritorious part of the profession are starving ; and yet, with the same breath, they vociferate, down with all barriers—let merit be the only test—if merit met with its reward we should not be without practice, and our great champion would be at the head of his profession, instead of being restricted for a fortnight to a single patient—"a decent woman, lodging in Avery-Row." That distress does prevail in our profession, as well as in most other departments of the community, we cannot doubt. But while we admit this fact, and would willingly, in any reasonable manner, make our Journal instrumental to the relief of our suffering brethren, we must at the same time express our strong conviction that, in the great majority of cases, entire failure in practice is dependent upon incapacity or imprudence on the part of the individual ; and that they who now hunger after bread, are chiefly those persons who, in early life, never thirsted after knowledge. But from whatever cause the evil may arise, is it not a monstrous absurdity, with the fact of the profession being already too much crowded staring us in the face, to demand such changes in the system of education as would immediatel

render admission into it more easy, and success, when admitted, more difficult? In our opinion it ought, with all the corporate bodies, to be a fundamental principle to raise, rather than to depress, the standard of education; and every fair and rational means to accomplish the former object shall receive what assistance our humble support can afford it.

But to return. There is one rather amusing contradiction in the present regulations of the College of Surgeons, as to the period of study required; and which, if not a mere oversight, would seem to evince the very Quixotism of disinterestedness, instead of that abandoned devotion to Mammon which we are weekly assured the members of the council unanimously betray. It is, that candidates are required to bring proof "of having been engaged six years in the acquisition of professional knowledge." And again—

"Members and licentiates in surgery, of any legally constituted College of Surgeons in the united kingdom, and graduates in surgery of any university requiring residence to obtain degrees, will be admitted for examination on producing their diploma, license, or degree."

Now, as in other places four years is the minimum duration of study required, it is quite clear that the shortest route to Lincoln's-Inn Fields is by the way of Dublin, Glasgow, or Edinburgh. By this arrangement, too, the student, in his curriculum, need not so much as come within sight of any of those "human slaughterhouses," the London Hospitals, or any of the "Vampires" who live upon the blood of the patients. We marvel that our ingenuous contemporary has not expatiated on the great advantages to which this must give rise.

The greatest defects, however, in our opinion, as to these new regulations, are, first, that no order of succession in which the different branches of study

shall be followed, is enjoined; and, secondly, that the period of hospital attendance is so short. With regard to the former, it is indeed "recommended" that candidates shall have studied anatomy by attendance on lectures, and by dissections, during one season prior to attending the practice of an hospital: but of what use is it to "recommend," when the neglect of the recommendation carries with it no forfeit? If the advice be proper (which unquestionably it is), then ought it to have been made imperative, and not left optional. Anatomy, as we have elsewhere stated, is the very elements of surgery; and it is as necessary that a pupil should be master of it before he enters upon the study of surgery by lectures or hospital attendance, as that a boy should learn the Latin grammar before he attempts to construe. If, as many do, the pupil enter to his anatomy and hospital at the same time, such arrangement is injurious to both pursuits, and ruinous to the latter. He dissects till the latest moment—arrives at the hospital, perhaps, when the surgeon is already come, and contents himself with forming part of his "tail" for an hour, or perhaps but half that time; then hurries back to the anatomical lecture. And this leads us to remark, that the hours selected for teaching the different branches of medicine in London, are essentially bad. It would be much better that all the anatomical business should be completed before visiting the hospital. Full time should then be given for this; say from 12 to 2, or from 1 to 3, after which should come the lectures on disease, whether medical or surgical, while the mind of the student is fresh from its contemplation. Thus would the objects presented to him follow each other in natural succession, without that loss of time and jumble of ideas which result from the present system. According to the ex-

isting arrangements, the student probably opens the day with dissecting a little; but scarcely has he well begun when he is obliged to leave off, that he may attend his lectures on *materia medica* and the practice of medicine—his mind yet occupied with the *subject* he has just left. The lecture being ended, back he goes to dissect or to demonstration; after which he hurries to the hospital—returns to his anatomy—and has his surgery in the evening. A certain degree of variety is necessary to keep up attention, but changes so numerous and rapid as these cannot fail to confuse, and the alternation of ideas in the pupil's mind, could it be shewn on paper, would present the departments of science as arbitrarily, but not so distinctly depicted, as the intellectual organs in one of Mr. Deville's casts, or "the provinces in a map of revolutionary France."

SENTENCE IN THE CASE OF CLAPHAM.

THE sentence of the law has been pronounced against John Clapham, the unfortunate and misguided youth whom Wakley brought forward as a witness against Mr. B. Cooper. He has been condemned to six months' imprisonment in the common gaol. This is one of the fruits of that system of deception practised upon the young and inexperienced, by which they are led to the belief, that the various Corporate Institutions of this country are illegal; because it suits the interested purpose of a flagitious journalist to call them so. This belief once adopted, the next step is easy. "If they be not lawful," say these sophists, "it cannot be unlawful to overreach them;" and thus do they commit those misdemeanors which are visited with such serious and disgraceful punishment—punishment which not only interferes with a young man's prospects for the time, but which

fixes a brand of infamy upon his brow which can never be effaced. We are the more anxious to insist upon this point, because we know that a large number of cases have lately occurred, in which attempts have been made to practise various deceptions upon the Society of Apothecaries. We beseech those who would avoid getting into trouble, if actuated by no better motive—to take warning by the case we now record.

"Mr. Justice BAYLEY, after the Judges had conferred together for a few minutes, addressed the defendant, and said that no man with proper feelings of morality, or proper feelings of integrity, could fail to shrink from the means which the defendant had adopted to procure his license from the Apothecaries' Company. The question was not one of fitness or unfitness in any particular individual to practise as an apothecary. The legislature had determined that no man should practise unless he had passed a regular examination before the Court of Examiners of the Apothecaries' Company, and that that Company should not be at liberty to grant a license to any person who should be under the age of 21 years. It had been represented by the affidavits that the defendant's father bore a most unexceptionable character, and that the character of the defendant himself, with this single exception, was also unimpeachable; but this was a most momentous exception; for no man of right feelings would ever have ventured to do that which the defendant had done. The sentence of the court was, that he be imprisoned in the gaol at Huntingdon for the county of Huntingdon, for the space of six calendar months, and in the meantime be committed to the custody of the Marshal of the Marshalsea."—*Times*, Nov. 20.

MR. EARLE'S LETTER.

MR. EARLE's letter, published in our last number, has excited a considerable *sensation* in more quarters than one. The manner in which the subject has been viewed by the gentlemen attending his Clinical Lectures must be as gra-

render admission into it more easy, and success, when admitted, more difficult? In our opinion it ought, with all the corporate bodies, to be a fundamental principle to raise, rather than to depress, the standard of education; and every fair and rational means to accomplish the former object shall receive what assistance our humble support can afford it.

But to return. There is one rather amusing contradiction in the present regulations of the College of Surgeons, as to the period of study required; and which, if not a mere oversight, would seem to evince the very Quixotism of disinterestedness, instead of that abandoned devotion to Mammon which we are weekly assured the members of the council unanimously betray. It is, that candidates are required to bring proof "of having been engaged six years in the acquisition of professional knowledge." And again—

"Members and licentiates in surgery, of any legally constituted College of Surgeons in the united kingdom, and graduates in surgery of any university requiring residence to obtain degrees, will be admitted for examination on producing their diploma, license, or degree."

Now, as in other places four years is the minimum duration of study required, it is quite clear that the shortest route to Lincoln's-Inn Fields is by the way of Dublin, Glasgow, or Edinburgh. By this arrangement, too, the student, in his curriculum, need not so much as come within sight of any of those "human slaughterhouses," the London Hospitals, or any of the "Vampires" who live upon the blood of the patients. We marvel that our ingenuous contemporary has not expatiated on the great advantages to which this must give rise.

The greatest defects, however, in our opinion, as to these new regulations, are, first, that no order of succession in which the different branches of study

shall be followed, is enjoined; and, secondly, that the period of hospital attendance is so short. With regard to the former, it is indeed "recommended" that candidates shall have studied anatomy by attendance on lectures, and by dissections, during one season prior to attending the practice of an hospital: but of what use is it to "recommend," when the neglect of the recommendation carries with it no forfeit? If the advice be proper (which unquestionably it is), then ought it to have been made imperative, and not left optional. Anatomy, as we have elsewhere stated, is the very elements of surgery; and it is as necessary that a pupil should be master of it before he enters upon the study of surgery by lectures or hospital attendance, as that a boy should learn the Latin grammar before he attempts to construe. If, as many do, the pupil enter to his anatomy and hospital at the same time, such arrangement is injurious to both pursuits, and ruinous to the latter. He dissects till the latest moment—arrives at the hospital, perhaps, when the surgeon is already come, and contents himself with forming part of his "tail" for an hour, or perhaps but half that time; then hurries back to the anatomical lecture. And this leads us to remark, that the hours selected for teaching the different branches of medicine in London, are essentially bad. It would be much better that all the anatomical business should be completed before visiting the hospital. Full time should then be given for this; say from 12 to 2, or from 1 to 3, after which should come the lectures on disease, whether medical or surgical, while the mind of the student is fresh from its contemplation. Thus would the objects presented to him follow each other in natural succession, without that loss of time and jumble of ideas which result from the present system. According to the ex-

isting arrangements, the student probably opens the day with dissecting a little; but scarcely has he well begun when he is obliged to leave off, that he may attend his lectures on *materia medica* and the practice of medicine—his mind yet occupied with the *subject* he has just left. The lecture being ended, back he goes to dissect or to demonstration; after which he hurries to the hospital—returns to his anatomy—and has his surgery in the evening. A certain degree of variety is necessary to keep up attention, but changes so numerous and rapid as these cannot fail to confuse, and the alternation of ideas in the pupil's mind, could it be shewn on paper, would present the departments of science as arbitrarily, but not so distinctly depicted, as the intellectual organs in one of Mr. Deville's casts, or "the provinces in a map of revolutionary France."

SENTENCE IN THE CASE OF CLAPHAM.

THE sentence of the law has been pronounced against John Clapham, the unfortunate and misguided youth whom Wakley brought forward as a witness against Mr. B. Cooper. He has been condemned to six months' imprisonment in the common gaol. This is one of the fruits of that system of deception practised upon the young and inexperienced, by which they are led to the belief, that the various Corporate Institutions of this country are illegal; because it suits the interested purpose of a flagitious journalist to call them so. This belief once adopted, the next step is easy. "If they be not lawful," say these sophists, "it cannot be unlawful to overreach them;" and thus do they commit those misdemeanors which are visited with such serious and disgraceful punishment—punishment which not only interferes with a young man's prospects for the time, but which

fixes a brand of infamy upon his brow which can never be effaced. We are the more anxious to insist upon this point, because we know that a large number of cases have lately occurred, in which attempts have been made to practise various deceptions upon the Society of Apothecaries. We beseech those who would avoid getting into trouble, if actuated by no better motive—to take warning by the case we now record.

"Mr. Justice BAYLEY, after the Judges had conferred together for a few minutes, addressed the defendant, and said that no man with proper feelings of morality, or proper feelings of integrity, could fail to shrink from the means which the defendant had adopted to procure his license from the Apothecaries' Company. The question was not one of fitness or unfitness in any particular individual to practise as an apothecary. The legislature had determined that no man should practise unless he had passed a regular examination before the Court of Examiners of the Apothecaries' Company, and that that Company should not be at liberty to grant a license to any person who should be under the age of 21 years. It had been represented by the affidavits that the defendant's father bore a most unexceptionable character, and that the character of the defendant himself, with this single exception, was also unimpeachable; but this was a most momentous exception; for no man of right feelings would ever have ventured to do that which the defendant had done. The sentence of the court was, that he be imprisoned in the gaol at Huntingdon for the county of Huntingdon, for the space of six calendar months, and in the meantime be committed to the custody of the Marshal of the Marshalsea."—*Times*, Nov. 20.

MR. EARLE'S LETTER.

MR. EARLE's letter, published in our last number, has excited a considerable *sensation* in more quarters than one. The manner in which the subject has been viewed by the gentlemen attending his Clinical Lectures must be as gra-

example, a man whose constitution is utterly enfeebled by intemperate habits, with whom there exists an absolute deficiency of vital power, both locally and generally, becomes infected with a venereal sore on the penis, which, in a man of healthy constitution, would readily yield to common means, but with him rapidly spreads, and the contiguous parts speedily become gangrenous. A similar condition of system may be engendered by a combination of circumstances operating upon a previously healthy habit; such as the profuse exhibition of mercury, and confinement in the crowded wards and tainted atmosphere of an hospital. It is scarcely necessary to say, that the two latter causes act upon a diseased habit with tenfold fury.

"After saying thus much of the pathology of sloughing venereal ulcers, it is unnecessary to enter into a minute detail of the requisite treatment, which here, as elsewhere, must be regulated by circumstances. I may briefly observe, that those cases which are obviously dependent upon increased vascular action, are most under control, as, by a judicious and early use of antiphlogistic means, it is in our power at once to arrest the progress of disease."

"Gonorrhœal Ophthalmia."

"It will not be considered irrelevant briefly to advert here to that most destructive form of ophthalmia which occasionally prevails during the progress of gonorrhœa, and which I believe to be in every instance produced by the direct application of the urethral discharge to the eye.

"The attack of this species of ophthalmia is generally very sudden: for the most part one eye only is affected, but occasionally the disease affects both, and there is then sometimes, though not generally, a diminution or suppression of the disease from the urethra. The seat of the disease, in the first instance, is in the membrana conjunctiva, which becomes red and swollen to a great degree, and with a rapidity which has no parallel in any other condition of this organ. The inflammation quickly extends to the cornea; a profuse purulent discharge takes place from within both the upper and lower palpebræ; the vessels of the transparent cornea become injected with red blood, and complete chemosis often ensues in forty-

eight hours, or even less. The rapidity with which the conjunctiva becomes engorged is sometimes truly astonishing, everting both the lids; and the discharge is profuse beyond what could be conceived, either from the space which affords it, or the time in which the disease runs its course. The pain attending it is extreme, and the symptoms of constitutional disturbance very severe. The inflammation extends into the interior of the eye, producing a sudden effusion of lymph into the anterior chamber, and ultimately ulceration or rupture of the cornea, and consequent destruction of the eye.

"It is obvious that in the treatment of these cases—where disease runs its course with such frightful rapidity—we must be proportionally active in our remedial means. Large blood-lettings, repeated according to circumstances, and the exhibition of tartrate of antimony, so as to induce and keep up nausea and faintness, are two of the most powerful agents in subduing inflammation. But my experience in the treatment of this disease leads me to prefer the exhibition of calomel in conjunction with the antimony; as, for instance, if we suppose an extreme case in which blood has been quickly abstracted to the amount of thirty, and I have sometimes bled even to forty ounces, I then commence with two grains of calomel and a quarter or a sixth of a grain of tartrate of antimony every hour or two.

"The pre-eminent value of calomel in arresting acute inflammation of *serous* membranes is so well known, and the remedy so generally had recourse to, that it would be superfluous to say any thing on that point; but I have always been of opinion that the importance of calomel in arresting acute inflammation of *mucous* membranes has not been sufficiently acted upon. If I should not be considered as entirely deviating from my subject, I would specially notice the utility of mercury in cases of acute inflammation of the lining membrane of the larynx, trachea, and bronchi.

"It must, however, be confessed, that in a great majority of cases, although from the beginning the disease may be treated in the most prompt and energetic manner, yet the means will prove insufficient.

"From a conviction of the insufficiency of the antiphlogistic treatment,

though pushed to the utmost extreme, in subduing this species of ophthalmia, a practice diametrically reverse in its nature has recently been adopted by several army surgeons. It consists in dropping into the eye a strong solution of nitrate of silver; ten, fifteen, or twenty grains to an ounce of distilled water. This practice is had recourse to in the commencement of the severest form of conjunctival ophthalmia; and it is said, that so far from producing, as might be supposed, any increase of pain, it is attended with the most decided advantages; the pain and redness of the membrane being overcome almost immediately, and the cure effected, even without the abstraction of blood. The testimonies in favour of this practice in conjunctival inflammation are, I must acknowledge, so satisfactory, that I should not hesitate to adopt it in gonorrhœal ophthalmia.

"There is a kind of chronic ophthalmia which occurs in conjunction with the rheumatic pains and swellings of the joints already described as occasionally taking place in the progress of gonorrhœa. This affection is very different from the formidable disease which I have just described. It appears that the conjunctiva, in common with the other mucous membranes of the body, is in a disordered condition; and it is worthy of remark, that in some instances this ophthalmic affection alternates with the pains in the limbs."

"Fungus of the Testicle."

"This disease is by no means of rare occurrence. Sometimes phlegmonous inflammation of the testicle terminates in a small abscess, which bursts, and from the ulcerated opening the fungus gradually protrudes. In other cases, a painful swelling of the testicle, particularly characterized by its hardness, is the first symptom of the disease. After an uncertain period of time, the integuments, growing gradually thinner, ulcerate; and after a slight discharge of matter, a firm and generally insensible fungus protrudes; the surrounding integuments are much thickened and indurated, so that there appears a considerable mass of disease; the pain abates, and the swelling subsides considerably after the integuments have given way. In this state the disorder appears very indolent; but if the fungus be destroyed by any means, the integuments come together, and a cicatrix is formed.

"The fungus has its origin in the glandular substance of the testis itself, the coats of which are destroyed to a certain extent, and a protrusion of the tubuli seminiferi takes place through the aperture. Sometimes, however, a fungous growth arises only from the tunica albuginea, the testicle itself being sound.

"In many instances the disease seems to be caused or accompanied by a morbid condition of the lining membrane of the urethra.

"The state of the testicle will serve to distinguish this disease from those fungi of a malignant character which frequently are situated on this part, and usually are the result of cancer or fungus hæmatodes of this organ, and wherein early extirpation is the only treatment which offers a chance of relief.

"It is to be remembered, in the treatment of this affection, that the fungus has no character of malignity attached to it, and consequently castration is never requisite, as regards the disease simply. With a view of bringing the case to a speedy termination, when the structure is so far destroyed that the discerning powers of the organ are lost, we may recommend complete extirpation; but in a majority of cases, by early attention, a milder treatment will suffice.

"When the disease has clearly originated in consequence of irritation communicated to the testicle by a morbid state of the urethra, the swelling will frequently subside, the fungus shrink, and a complete cure will be effected, on the removal of the cause by the means recommended in treating of disorders of the urinary passage. It is probable, indeed, that in other cases a cure might be accomplished by the unaided efforts of nature; the disease, however, is of so indolent a character that a spontaneous cure would prove a tedious process.

"The fungus may be removed with the knife, by ligature, or by escharotics; and likewise it may be got rid of by absorption under the use of pressure constantly applied. If the projection be large, it is perhaps the best practice to cut off the fungus, and having pared the hardened edges of the integuments, to bring them as closely in apposition as possible. The treatment by ligature is tedious. Of the escharotic applications, the nitrate of silver is preferable; it should be applied freely, dry lint should then be put over the part, and firm pressure made use of by the appli-

dent that gave rise to this man's complaint), the curve is more acute, since it is constituted by the deviation of no less than seven vertebræ from their places. But although, by the undermining of the columnar, or the anterior part of the spine, the projection is generally forward, there is nothing to prevent the bodies of the vertebræ giving way towards one side, and producing, therefore, a degree of lateral twist which might lead the practitioner to conceive that he had to deal with a case of lateral distortion. We have an instance of this in the case of Akers.

Emma Akers, æt. 7, Northumberland Ward, was admitted Nov. 10th, with curvature of the spine, attended with distortion of the bones of the chest. The spinous process of the third or fourth dorsal vertebra projects, and there is a slight bend to the left, by which the right shoulder is elevated higher than the left. There is no paralysis. She complains of pain on the left side, near the cartilages of the false ribs, and she attributes this to one of her companions striking her here. Her mother used every morning to press heavily upon the right shoulder, to reduce it to the same level with the left; and this gave great pain to the little girl, especially near the margins of the chest. She has been relieved of the pain in her side by the application of issues to the projecting part of the spine. It is not possible to rely on the account which she gives of the origin of the complaint.

In this case, you will observe that the distortion is lateral, and has the usual effects upon the shoulders. Yet the case is one of scrofulous disease of the vertebræ. But to recal us to the proper subject, I shall take the case of Langhurst.

Edward Langhurst, æt. 21, a farmer's servant, was admitted into Hertford Ward, November 3d, with complete paralysis of the muscles of the lower extremities, the sensation remaining perfect. He states that two years ago, after having caught cold from being exposed to the rain, he first began to feel pain in his stomach: this pain never left him, and he got weaker, so that in the course of a year he had great difficulty in doing his work.

Eight months ago, he lost the power of moving his limbs, and there was a numbness extending all the way from the umbilicus to the toes. Three weeks before he presented himself at the hospital, the sensation returned to the limbs; so that it was quite natural. He was easily purged, and then his stools passed involuntarily: he lost the

power of retaining his urine. He declared that he had no pain in his back. On examination, the spinous processes of the vertebræ in the centre of the back were seen to project, but not to a very great degree.

He died on the same night as the patient Field, and it was thought that he was very much alarmed by seeing this patient, who had the same complaint as himself, dying. His previous symptoms did not seem to indicate that his death was so near.

Dissection.—The bodies of these vertebræ in which the spines were seen to project, were fallen together, and were surrounded by much thickened cellular membrane. There were adhesions between the liver and the diaphragm, but there was no other remarkable morbid appearance in the chest or abdomen.

You see enough, then, of the scrofulous disease and wasting of the bodies of the vertebræ. The anatomical examination of the spine must have informed you that the vertebræ are of that class of bones, light and spongy in their interior texture, with a very thin cortex, which are exposed to scrofulous disease, and which are apt to take this peculiar inflammation upon them when injured. You perceive the chasm that is left by the absorption of the bodies of the vertebræ, and can determine on the impropriety of that treatment in which the patient is raised by instruments, or extended horizontally. No doubt the spine may be made straight and the height increased, by this treatment, so as to give rise to flattering anticipations: but the ill adjustment of the instrument endangers the sudden falling down of the spine, by which the spinal marrow may be injured to a fatal degree. You also see, by these other specimens, the process of cure: that it is by the ankylosis of the bodies of the vertebræ and the cessation of motion; it is by the removal of the motion, which is the great source of irritation, that the inflammation also ceases. How can all this take place if the remaining surfaces of the diseased vertebræ be held apart by means of instruments? I am not now arguing against the employment of proper means, but the abuse of them. The instruments must be employed to steady the trunk against lateral motion, and to sustain the weight of the upper part of the body—thereby to prevent the pressure and attrition of the inflamed surfaces of the bones, but not to separate the surfaces.

[To be concluded in the next number.]

would be likely otherwise to obtain ; and therefore it is fair to presume that the stock of knowledge which he lays in will be more extensive than if no such provision existed. Now if this be the test by which the measure is to be tried, we think there can be no doubt of its expediency. Neither have we any hesitation in affirming that the pupil who passes the first years of his professional studies in a provincial town, and comes to London with his mind already cultivated and prepared to receive every addition with avidity, will become a more accomplished surgeon than one whose education has begun and ended either in a provincial town or in the metropolis. One advantage, of no inconsiderable value, thus secured to him, will be that of attending the practice of two different hospitals. Any man who has seen much of our profession must have observed how apt the student is to pin his faith to the dicta of his teacher, adopting not only his opinions, but often his prejudices with them. If he settles in life at once, without an opportunity of witnessing the practice of others, his views remain permanently limited ; he sees only through the medium to which he has been accustomed ; or if he acquires a habit of seeing and thinking for himself, it is after a much longer period, and much more extensive experience. But if he attends in early life the practice and lectures of competent persons at different schools, he soon feels the necessity of judging for himself, and acquires a habit of referring to the book of nature as the only unerring authority by which the value of conflicting opinions can be duly estimated.

Were it left for the student to pursue what course his fancy might suggest ; were he told to acquire knowledge when and where he chose, without any defined curriculum, the standard of education would necessarily be lowered, and the door opened wide to the admission of a

crowd of persons from the lower classes of the community, who would be tempted, by the increased facilities and diminished expense, to enter a profession already over stocked. Every operative in Manchester would endeavour to make his son a *doctor* and a *gentleman*, till, in a few years, the unfortunate youth would envy the mechanical occupation of his father, and think that a village over-stocked with surgeons was worse than a market glutted with silks.

The outcry of the *levellers* (who, by the way, are now reduced to a few disappointed individuals, "the cankers of a calm world and a long peace,") is, that the meritorious part of the profession are starving ; and yet, with the same breath, they vociferate, down with all barriers—let merit be the only test—if merit met with its reward we should not be without practice, and our great champion would be at the head of his profession, instead of being restricted for a fortnight to a single patient—"a decent woman, lodging in Avery-Row." That distress does prevail in our profession, as well as in most other departments of the community, we cannot doubt. But while we admit this fact, and would willingly, in any reasonable manner, make our Journal instrumental to the relief of our suffering brethren, we must at the same time express our strong conviction that, in the great majority of cases, entire failure in practice is dependent upon incapacity or imprudence on the part of the individual ; and that they who now hunger after bread, are chiefly those persons who, in early life, never thirsted after knowledge. But from whatever cause the evil may arise, is it not a monstrous absurdity, with the fact of the profession being already too much crowded staring us in the face, to demand such changes in the system of education as would immediatel

render admission into it more easy, and success, when admitted, more difficult? In our opinion it ought, with all the corporate bodies, to be a fundamental principle to raise, rather than to depress, the standard of education; and every fair and rational means to accomplish the former object shall receive what assistance our humble support can afford it.

But to return. There is one rather amusing contradiction in the present regulations of the College of Surgeons, as to the period of study required; and which, if not a mere oversight, would seem to evince the very Quixotism of disinterestedness, instead of that abandoned devotion to Mammon which we are weekly assured the members of the council unanimously betray. It is, that candidates are required to bring proof "of having been engaged six years in the acquisition of professional knowledge." And again—

"Members and licentiates in surgery, of any legally constituted College of Surgeons in the united kingdom, and graduates in surgery of any university requiring residence to obtain degrees, will be admitted for examination on producing their diploma, license, or degree."

Now, as in other places four years is the minimum duration of study required, it is quite clear that the shortest route to Lincoln's-Inn Fields is by the way of Dublin, Glasgow, or Edinburgh. By this arrangement, too, the student, in his curriculum, need not so much as come within sight of any of those "human slaughterhouses," the London Hospitals, or any of the "Vampires" who live upon the blood of the patients. We marvel that our ingenuous contemporary has not expatiated on the great advantages to which this must give rise.

The greatest defects, however, in our opinion, as to these new regulations, are, first, that no order of succession in which the different branches of study

shall be followed, is enjoined; and, secondly, that the period of hospital attendance is so short. With regard to the former, it is indeed "recommended" that candidates shall have studied anatomy by attendance on lectures, and by dissections, during one season prior to attending the practice of an hospital: but of what use is it to "recommend," when the neglect of the recommendation carries with it no forfeit? If the advice be proper (which unquestionably it is), then ought it to have been made imperative, and not left optional. Anatomy, as we have elsewhere stated, is the very elements of surgery; and it is as necessary that a pupil should be master of it before he enters upon the study of surgery by lectures or hospital attendance, as that a boy should learn the Latin grammar before he attempts to construe. If, as many do, the pupil enter to his anatomy and hospital at the same time, such arrangement is injurious to both pursuits, and ruinous to the latter. He dissects till the latest moment—arrives at the hospital, perhaps, when the surgeon is already come, and contents himself with forming part of his "tail" for an hour, or perhaps but half that time; then hurries back to the anatomical lecture. And this leads us to remark, that the hours selected for teaching the different branches of medicine in London, are essentially bad. It would be much better that all the anatomical business should be completed before visiting the hospital. Full time should then be given for this; say from 12 to 2, or from 1 to 3, after which should come the lectures on disease, whether medical or surgical, while the mind of the student is fresh from its contemplation. Thus would the objects presented to him follow each other in natural succession, without that loss of time and jumble of ideas which result from the present system. According to the ex-

isting arrangements, the student probably opens the day with dissecting a little; but scarcely has he well begun when he is obliged to leave off, that he may attend his lectures on *materia medica* and the practice of medicine—his mind yet occupied with the *subject* he has just left. The lecture being ended, back he goes to dissect or to demonstration; after which he hurries to the hospital—returns to his anatomy—and has his surgery in the evening. A certain degree of variety is necessary to keep up attention, but changes so numerous and rapid as these cannot fail to confuse, and the alternation of ideas in the pupil's mind, could it be shewn on paper, would present the departments of science as arbitrarily, but not so distinctly depicted, as the intellectual organs in one of Mr. Deville's casts, or "the provinces in a map of revolutionary France."

SENTENCE IN THE CASE OF CLAPHAM.

THE sentence of the law has been pronounced against John Clapham, the unfortunate and misguided youth whom Wakley brought forward as a witness against Mr. B. Cooper. He has been condemned to six months' imprisonment in the common gaol. This is one of the fruits of that system of deception practised upon the young and inexperienced, by which they are led to the belief, that the various Corporate Institutions of this country are illegal; because it suits the interested purpose of a flagitious journalist to call them so. This belief once adopted, the next step is easy. "If they be not lawful," say these sophists, "it cannot be unlawful to overreach them;" and thus do they commit those misdemeanors which are visited with such serious and disgraceful punishment—punishment which not only interferes with a young man's prospects for the time, but which

fixes a brand of infamy upon his brow which can never be effaced. We are the more anxious to insist upon this point, because we know that a large number of cases have lately occurred, in which attempts have been made to practise various deceptions upon the Society of Apothecaries. We beseech those who would avoid getting into trouble, if actuated by no better motive—to take warning by the case we now record.

"Mr. Justice BAYLEY, after the Judges had conferred together for a few minutes, addressed the defendant, and said that no man with proper feelings of morality, or proper feelings of integrity, could fail to shrink from the means which the defendant had adopted to procure his license from the Apothecaries' Company. The question was not one of fitness or unfitness in any particular individual to practise as an apothecary. The legislature had determined that no man should practise unless he had passed a regular examination before the Court of Examiners of the Apothecaries' Company, and that that Company should not be at liberty to grant a license to any person who should be under the age of 21 years. It had been represented by the affidavits that the defendant's father bore a most unexceptionable character, and that the character of the defendant himself, with this single exception, was also unimpeachable; but this was a most momentous exception; for no man of right feelings would ever have ventured to do that which the defendant had done. The sentence of the court was, that he be imprisoned in the gaol at Huntingdon for the county of Huntingdon, for the space of six calendar months, and in the meantime be committed to the custody of the Marshal of the Marshalsea."—*Times*, Nov. 20.

MR. EARLE'S LETTER.

MR. EARLE's letter, published in our last number, has excited a considerable *sensation* in more quarters than one. The manner in which the subject has been viewed by the gentlemen attending his Clinical Lectures must be as gra-

in every form of extensive burn, as the impaired functions of the integuments of the body would throw an additional burthen on the lungs. You are well aware that, in a state of health, there is a constant transpiration going on from the whole surface : when this is checked by sudden cold, pneumonia or pleurisy, or peritonitis, not unfrequently ensues. Exactly the same effect is produced by extensive burns or scalds which necessarily interfere with this most important function of the skin. When you have reason to suspect this to be the case, bleeding, both general and local, may be required ; but generally salines, particularly small and repeated doses of nitrate of potash, by increasing the action of the kidneys, will render this unnecessary. It occasionally happens, that even in these slighter burns the constitution participates, and severe rigors occur, with much depression of the vital powers. Of course, when such circumstances take place, the employment of cold is prohibited.

Let us now consider the opposite, or stimulating treatment, as applicable to such cases. This plan is also of great antiquity. Aristotle recommended that the burnt or scalded part should be exposed to the heat of the fire, to "draw out" the fire, on the well-known principle, probably, of the sun extinguishing a common fire. A long list of illustrious names might be adduced in favour of this plan—not to omit Shakspeare, who says,

"Fire cools fire within the scorched veins of one new burnt."

But I will not detain you further than by saying that it is now exploded, as causing much and unnecessary pain, and as perfectly inadmissible in any extensive burn. A host of stimulating applications have had their advocates in different ages ; and in looking dispassionately over the authorities and experience which have been recorded, it cannot be denied that very many cases have terminated by resolution, under every modification of treatment. It will, perhaps, be best to cut this Gordian knot, by simply referring these cases, not to any specific agency in the remedies employed, but to the efforts of nature, which, in many cases, in spite of every thing, will be crowned with success. Different oils, and various unctuous substances, have been highly extolled, and no doubt they are frequently beneficial. To me it appears that the benefit to be

derived from them all may be referred to one common principle — namely, excluding the air from the inflamed surface ; which never fails to stimulate the parts, and to excite an injurious degree of reaction. These observations apply with tenfold force to cases of the second and third order, where the inflamed cutis is exposed ; but even when the surface is not abraded or broken, the oxygen of the atmospheric air appears to stimulate the minute arteries of the part already in a state of over-action. On this principle of excluding the air, the benefit said to accrue from some more modern applications may be readily explained. The greatly extolled cotton-wool, the covering the part with flour or fullers'-earth, or finely levigated lime, all admit of the same solution. As far as my own experience goes, one of the best applications in such cases is fine old cloth, dipped in a liniment of lime-water and oil. The lime, which is held in solution, completely fills up the interstices of the cloth, and effectually excludes the air, whilst the oil renders it so pliant that it may be accurately applied to every surface and cavity. The same effect may be produced by sprinkling the part freely with carbonate of lead, and applying over it cloth smeared with any simple ointment. Whatever remedy is employed, it should be nicely adapted to the whole surface, and not removed for some days.

If these means fail to produce a cure by resolution, vesication will take place to a greater or less extent, constituting the second form or degree of injury from the application of heat. Vesications will sometimes be speedily produced where the heat has been applied during some interval of time ; at other times they follow in a regular train, as consequences of the inflammation which has been excited in the integuments. An important practical question here arises : how are these vesications to be treated ? I do not hesitate to recommend, that, if possible, they should be preserved unbroken for at least forty-eight hours, unless, from their size, there be a risk of their bursting or being broken, and are productive of distress from the tension they keep up. Under these circumstances, they may be punctured with a fine needle introduced under the scales of the cuticle, so as to evacuate the vesicle gradually, without admitting air to the inflamed and de-

nuded cutis, the consequence of which exposure most commonly is extensive suppuration, if not sloughing of the integuments. It is best not to empty the bladders entirely, but to take off the tension from them, and then apply lime-water, or some unctuous substance, calculated to close the aperture and exclude the air. The action of the lime water, or the liniment of lime and oil, is well illustrated by the familiar experiment of dipping eggs in lime-water, which will prevent their becoming putrid for an indefinite length of time, by closing all the pores of the shell and excluding the air.

In the second form of burns, it most commonly happens that some part of the injured surface is denuded of its cuticular covering, leaving a highly inflamed surface, in a state of the greatest excitement, exposed to the action of the air. The great object to be attended to in these cases, is, as speedily as possible, to protect this surface by some application which shall exclude the air. Various unctuous applications have been recommended, but of all those which I have seen employed, and used myself, the most beneficial are the liniment of linseed-oil and lime-water, and the liniment of turpentine and ung. resin. flav. of which latter application I shall presently have to speak more at large, when treating of the third species of burns.

In burns followed by extensive vesications, the constitution will often seriously participate. There will be rigors, followed by fever, and much disturbance of the digestive functions and nervous system, which will call for watchful attention, and require to be treated on those principles which should regulate your practice in all similar cases.

When the surfaces have become exposed, and have ulcerated or sloughed, which will rarely occur if the part be speedily covered and not exposed for many days, the ulcerated surface will most readily heal under the use of cerat. Calaminæ, or ung. Zinci.

I come now to speak of the third and most important kind of burn, or that in which more or less of the integuments and deeper seated parts are deprived of their vitality, either by the immediate violence of the heat applied, or as a consequence of the inflammation which is excited. These cases al-

most always are combined with the two former kinds, as it very rarely happens that the whole force of the fire is expended on any given spot. One part suffers more severely, and may lose its vitality, whilst those in the neighbourhood may be vesicated, or only inflamed. Nothing can be more varied than the aspect presented by severe burns. At one part there may be an appearance of deep red, whilst others are blistered, and a third may present the aspect of an eschar. The appearance of parts entirely deprived of vitality by the action of heat is usually a dirty white, with a semi-transparent look, and often the course of blood-vessels, with dry coagulated blood, may be seen crossing in different directions. Around these dead portions, the integuments have the deepest red, bordering on gangrene, which is gradually lost as you approach the more healthy skin. At other times, when the parts are very deeply destroyed, the eschar has a black appearance, nearly similar to the dry gangrene which attacks the toes of old people. It is often very difficult at first sight to form any correct opinion of the extent and depth to which this destructive process may have gone. As burns are produced by such various substances, whose capacity for caloric is so very different, it follows that very dissimilar results will ensue from their application. The duration of their application, and the peculiar temperament of the individual, will also often modify the extent of injury. All burns of this description must be regarded as most serious injuries, and claim our especial attention. The constitutional symptoms which accompany them are always severe; the extremities are generally cold, and the patient experiences rigors, which recur at irregular intervals, and are, in general, in proportion to the extent, and depth, and importance of the part burnt. Exposure to cold greatly increases these rigors, so that you generally have an opportunity of witnessing this phenomenon when a patient is first admitted into the hospital. The pulse is frequent, and very small. The respiration is often laborious. The stomach is irritable, and rejects food: hiccup ensues, and the patient sinks into a state of coma, in which he often expires in a few hours, or after an interval of from one to two

days. If the patient survives this first stage, he may fall a victim to the symptomatic fever which ensues at any period during the first fortnight. During this period, also, it not unfrequently happens that serious inflammation of the serous or mucous membranes of the viscera takes place, which may claim our greatest attention, and require a treatment very opposite to that which the local injury would appear to indicate. These febrile symptoms generally abate after the first fortnight, and if the case terminates unfavourably after this period, the patient sinks from his vital powers being worn out by copious discharge and continual suffering, and he dies completely hectic.

In the treatment of these serious burns, it is generally necessary to administer some cordial internally, combined with opiates. Whenever the pulse is very small and feeble, the extremities cold, and there exists a disposition to rigors, it will be right to give warm brandy and water, or ammonia, with from 5 to 60 minims of laudanum, according to the age. When the vital powers are not depressed, and the patient suffers much, the opium may be given without the others. Considerable judgment is required in administering cordials. The great advocate for this plan, Mr. Kentish, appears to have entertained some very visionary notions, which are mixed up with his really valuable and practical observations, for which the world are deeply indebted to him. He advises the giving powerful stimuli internally, on the principle of counter-irritation; and he advocates the perseverance in their use for several days, until secretion takes place. It is true that he gives some strong facts in illustration of his plan; but I could produce equally powerful ones to prove, that such a plan is most injurious, and directly opposite to the dictates of common sense, and all the principles laid down for the treatment of inflammation. To adduce one memorable instance in which this stimulating treatment was injuriously persevered in, I will mention the cases of the fire-men who suffered at the burning of Covent Garden Theatre. Several of these unfortunate individuals were admitted into this hospital, and died with every symptom of inflammation of the membranes of the brain and mucous linings of the lungs. The stimulating plan was car-

ried to too great an extent in these cases, as was proved by examination after death. If the vital powers are greatly depressed, you may administer a cordial, and even repeat it until reaction has taken place; but when once that has occurred, it can rarely, if ever, be necessary to persevere in such a plan. When the first stage is passed, light and nutritious farinaceous food should be given, and the bowels gently regulated. Opiates will often be required for some time, to allay pain and irritation. Diarrhœa sometimes supervenes, and is occasionally beneficial where the discharge from the ulcers is very copious. From observing the good effects of spontaneous diarrhœa, when the discharge was profuse, and the rapidity with which the skinning process took place in some cases, Mr. Kentish strongly recommended the use of purgatives under these circumstances, and I have known them very useful. The diarrhœa, however, ought to be carefully watched, as it may arise from a destructive inflammation of the mucous membrane, which may require all our means to control. In the latter stages of large burns, bark and the mineral acids, combined with occasional purgatives, and a nourishing diet, will be proper.

I come now to speak of the local treatment of these cases of severe burns, with destruction of integuments, on which so much has been written, and such a variety of opinions exist. It will be right, in the first place, to remind you, that whatever you employ, it matters not with respect to that part which has already lost its vitality. It is to the parts in the immediate vicinity—those in the highest state of inflammation, and threatening sphacelation, that our attention should be directed; and here I should be wanting in gratitude if I were to withhold the due meed of praise from Mr. Kentish, whose plan, with certain modifications, I have seen eminently successful. It is true that his theories are often visionary; that he has founded his practice on a supposed analogy between the treatment of frost-bitten parts and that of parts in a state of the highest excitement—an analogy which will not bear a close investigation, and in pursuing which he was led into more than one serious error; yet upon the whole, we are indebted to him for many most use-

ful suggestions. An experienced man, unprejudiced by favourite theories, will easily extract the good practical facts, and feel grateful for them, whilst he will smile at the ingenious and amusing hypotheses which were built upon them.

This treatment was founded on the principle of inducing an unity of action between the injured parts and the system, and he divides his treatment into the stimulating and equalizing stages. He recommends the application of stimulants, to excite the absorbent vessels of the injured parts to equal the increased action of the corresponding secreting system. In doing this he forgets that he cannot stimulate one set of vessels without also stimulating the other, which are already in a state of over-excitement. In following up his supposed analogy, and gradually diminishing the stimulus, he advises less stimulating dressings to be applied on the second and third days, even should the patient be perfectly easy. "When the pain has ceased, it will be advisable to desist from the application of the spirit of turpentine and ung. Resin. and employ on the second day, simple digestives and olive oil, and afterwards on the third and fourth, the ceratum Calaminæ." Now this appears to me to be one of the most serious errors into which his theory has led him; as I believe it to be far better practice to allow the patient to enjoy his state of repose and freedom from pain as long as possible, and to leave the dressings, which are applied on the immediate receipt of the injury, unchanged until suppuration be fully established. The patient will be thus rescued from much unnecessary fatigue, and a renewal of suffering which cannot fail to be detrimental, and produce increased constitutional irritation; and the practitioner will be saved, for some time at least, the pain of hearing those distressing screams which, if the subject of the accident be young, he will be obliged to submit to during the subsequent treatment. The plan of treatment which I have been in the habit of pursuing, with very happy effects, has been to bathe the parts with warm spirits of turpentine, and as speedily as possible carefully to envelop every part with linen thickly smeared with a liniment of spirit of turpentine and ung.

resin. flay, as recommended by Kentish. It is better entirely to surround the extremities when burnt, and to retain the dressings in contact with the whole surface with bandages not too tightly applied. The application which has been advocated, and the use of which was revived by Kentish, very closely resembles that which was employed by Hippocrates, consisting of hog's lard, resin, and bitumen. Thus, after the revolution of ages, we find the same remedies are often revived under new appellations, and perhaps with more philosophic views. This application appears very soothing, and the young patient will sometimes cease to cry, and fall asleep as soon as dressed. Having nicely covered every part of the burnt surface with the dressing, and administered a cordial with opium, according to the rules I have laid down, the patient is suffered to remain quiet, and the dressing should not be disturbed for several days—not until suppuration is fully established. If on removing the dressings, deep sloughs present themselves, there is no better application than warm emollient poultices. After the separation of the sloughs, the wounds must be treated like common ulcers, a subject to enter on which at present would occupy too much time.

There are, however, two or three points of practice on which I will for a moment dwell. One has reference to the dressing an extensive burn which has a disposition to throw out exuberant granulations. I have often seen patients put to much unnecessary pain by the whole surface being rubbed over with nitrate of silver, or other escharotics: now this can never be necessary, as such wounds heal only from their edges, and although the skinning process will be often much assisted by touching the edges of the sore with the nitrate of silver, it cannot be necessary to rub it over the whole surface. One of the best applications in the secondary treatment of extensive burns is a bread poultice, moistened with a solution of chloride of soda. The warmth and moisture are very favourable to cicatrization, and the chloride of soda appears to exert a peculiar influence over the cuticle, and to prevent the formation of those hard rigid cicatrices, which so often occur. The other point is with respect to the

days. If the patient survives this first stage, he may fall a victim to the symptomatic fever which ensues at any period during the first fortnight. During this period, also, it not unfrequently happens that serious inflammation of the serous or mucous membranes of the viscera takes place, which may claim our greatest attention, and require a treatment very opposite to that which the local injury would appear to indicate. These febrile symptoms generally abate after the first fortnight, and if the case terminates unfavourably after this period, the patient sinks from his vital powers being worn out by copious discharge and continual suffering, and he dies completely hectic.

In the treatment of these serious burns, it is generally necessary to administer some cordial internally, combined with opiates. X

The journal of these transactions has, at all times subsequently, been open to every member of the profession—during the summer season at the Infirmary, at other times at my own laboratory. In that journal, p. 1264, the mode of preparing the *Liquor Opii Sedativus* is explained.

The lectures and demonstrations were intended to have been resumed, at the infirmary, on the 27th of May of the present year, in the printed announcement of which is the following paragraph:—"Analyses of several articles of the materia medica, but especially of opium and of the *cinchona cordifolia*, have been publicly conducted. The efficiency of cold infusions, and the superiority of extracts obtained from them, by a heat not exceeding 120 or 130 degrees, has been proved. In conducting or repeating these processes, numerous very concentrated solutions have been obtained, and made available for medical purposes." This intended course was, however, prevented by the unfortunate indisposition of Dr. Farre.

In the first and only number yet published of the "*Journal of Morbid Anatomy*," &c. which appeared at the latter end of last year, I communicated a paper on the analysis of *cinchona cordifolia*, and another on *Barbadoes aloes*, to which I refer.

The mode of preparing the *liq. opii sed.* has been, for some time, in possession of the Royal College of Physicians, and that learned body will make such use of the communication, if any, as it shall deem proper, in the next edition of the *Pharmacopœia* of the college.

I trust, sir, I have said enough to show, that I have not been unfaithful to my pledge, expressed or implied, to disclose my processes to the profession, and to that object I now confine myself, leaving to the reflection of the writer and of your readers, the language and tone in which T. L. has thought proper to address you, and through you, the professional public. I am, Sir,

Your obedient servant,

RICHARD BATTLEY.

London, 1st Dec. 1829.

MENTAL DERANGEMENT FROM GASTRIC IRRITATION.

By H. WORSHIP, M.R.C.S.

EDMUND —, aged 15, but not yet arrived at puberty, of small stature, but regularly formed, with light-coloured hair, delicate and pale skin, and an active and intelligent mind, was put under my care for an affection of his eyes, which presented the following appearances:—There is in each eye a pencil of red vessels, running from the external and internal angle, and terminating at the margin of the cornea, which is perfectly transparent; the pupil is large and regular; the iris acts slowly and almost imperceptibly when a strong light is admitted to the eye, and the pupil becomes contracted only when the sight is fixed on any particular object; the conjunctiva of the lids inflamed, and there is lachrymation and confusion of vision when an object is regarded for any length of time. The upper eyelid is large from the number and size of its vessels. He has been subject to similar attacks from time to time during the last four or five years, and has lately been under the care of a celebrated oculist, who has advised the application of leeches, and an occasional dose of calomel, to be followed up with senna and salts.

His mother informed me that he was not sound in his mind; and with respect to this point, I made out the following history. About two years since he was the subject of scarlet fever, which ran rather high. He had passed nearly a week in convalescence from the attack, when he was seized with acute pain in the abdomen, followed by purging and vomiting, which continued for some hours. It was then his mind became affected; he screamed, and made such exertions, that he was with difficulty kept in his bed; he fancied he was going to be murdered, and pointed at the imaginary objects which were to destroy him. He would minutely detail many absurd stories, of which he had no memory when subsequently questioned. From this state he passed into one nearly resembling idiotism, and then gradually recovered. Although occasionally irritable, he has had no attack like the one I have just described till within a short time of my attendance,

ner was this attack of so severe a character as its predecessor.

Disregarding, for a time, the affection of the eyes, and bearing in mind the history of the former illness, I was induced to look for the cause of the present relapse in a disorder of the stomach, or some other abdominal viscus. That such a disorder existed, and that the treatment I adopted for its removal acted beneficially on the brain, the following statement will fully prove.

Nov. 3d.—My patient complains of great pain and heat in the head, with confusion of ideas. His pulse is quick and full; respiration short, and principally carried on by the ribs. He sighs continually; his digestion is painful, and his appetite immoderate, for scarcely does half an hour elapse after eating a meal, which would satisfy two persons, when he again calls for food, and eats to a like excess. The tongue is covered with a white fur; the bowels are irregular; the epigastrium is full and hard, and painful on pressure. He was put on low diet, with lemonade for drink; leeches, followed by poultices, were applied to the pit of the stomach on the 3d, 4th, and 8th; the leeches amounted in all to 40. To the treatment just mentioned, my patient added the occasional use of a foot-bath.

Nov. 14th.—His recovery has been as rapid as I could have wished: at the time I am writing, his tongue is clean, his head clear; the pain in the epigastrium no longer exists, and the inflammation of the eyes has quite disappeared; so that, he says, his sight is as good as ever it was.

It will readily be granted that there are many cases in which disorder of the stomach is the exciting cause of pains, and other unpleasant feelings in the head; but that this disorder, (be its character and symptoms what they may), should so far act on the cerebral mass as to produce a derangement of the intellectual functions, for any length of time, or at intervals, is a point which will less readily be believed from the want of facts to substantiate such an opinion. From the history of the first attack, as related to me by the lad's mother, I had already formed my suspicions respecting its cause. In the treatment I adopted when he came under my care, I was farther guided by the symptoms which then presented themselves; and the favourable result which

I obtained has justified me in the plan I pursued. Previously to my attendance, the lad had, unknown to his mother, obtained some leeches, and applied them to his head; the relief he experienced was slight, and of but short duration. The account of the affection of the eyes has been given in detail, that the cure, which was effected by the general treatment, and without local applications, may have its due importance. My object in publishing this case is to solicit the attention of medical men to the influence which gastric irritation possesses in producing disorders of the mind.

Nov. 20, 1829.

ANALYSES & NOTICES OF BOOKS.

“ L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Elements of Physics, or Natural Philosophy, General and Medical, explained independently of Technical Mathematics. In two volumes. Vol. II. Part I. Comprehending the subjects of Heat and Light. By NEIL ARNOTT, M.D. of the Royal College of Physicians.

AFTER an interval longer than we could have wished, a second volume of Dr. Arnott's interesting work lies upon our table. It embraces the subjects of Heat and Light, which are discussed in a very learned and agreeable manner, and enlivened by numerous illustrations borrowed from natural phenomena. The author's style is very copious and ornamental, and the perfection of the eye affords a fit theme for enthusiastic eulogy. We fully agree with Dr. Arnott that “the mind which can suppose or admit that within any limits of time, even a single such organ of vision could have been produced by accident, or without design,—and still more, that the millions which now exist on earth, all equally perfect, can have sprung from accident—or that the millions of millions in past ages were all but accidents—and that the endless millions throughout the animate creation, where each requires a most peculiar fitness to the nature and circumstances of the

animal, can be accident—must surely be of extraordinary character, or must have received unhappy bias in its education.”

There is but little in the volume strictly medical, as the subjects to which it relates scarcely admitted of this. One part, however, we must extract, though it is given as an appendix to the early editions of volume 1. It relates to the annoying, and often most inveterate habit of stuttering; and the suggestions thrown out by Dr. Arnott are ingenious and practical.

“The most common case of stuttering, however, is not, as has been almost universally believed, where the individual has a difficulty in respect to some particular letter or articulation, by the disobedience, to the will or power of association, of the parts of the mouth which should form it, but where the spasmodic interruption occurs altogether behind or beyond the mouth, viz. in the glottis, so as to affect all the articulations equally. To a person ignorant of anatomy, and therefore knowing not what or where the glottis is, it may be sufficient explanation to say, that it is the slit or narrow opening at the top of the windpipe, by which the air passes to and from the lungs—being situated just behind the root of the tongue. It is that which is felt to close suddenly in hiccup, arresting the ingress of air, and that which closes, to prevent the egress of air from the chest of a person lifting a heavy weight or making any straining exertion; it is that also, by the repeated shutting of which, a person divides the sound in pronouncing several times, in distinct and rapid succession, any vowel, as o, o, o, o. Now the glottis during common speech need never be closed, and a stutterer is instantly cured if, by having his attention properly directed to it, he can keep it open. Had the edges or thin lips of the glottis been visible, like the external lips of the mouth, the nature of stuttering would not so long have remained a mystery, and the effort necessary to the cure would have forced itself upon the attention of the most careless observer; but because hidden, and professional men had not detected in how far they were concerned, and the patient himself had only a vague feeling of some difficulty, which, after straining, grimace, gesticulation, and sometimes almost general convulsion of the body, gave way, the

uncertainty with respect to the subject has remained. Even many persons who by attention and much labour had overcome the defect in themselves, as Demosthenes did, have not been able to describe to others the nature of their efforts, so as to ensure imitation: and the author doubts much whether the quacks who have succeeded in relieving many cases, but in many also have failed, or have given only temporary relief, really understood what precise end in the action of the organs their imperfect directions were accomplishing.

“Now a stutterer, understanding of anatomy only what is stated above, will comprehend what he is to aim at, by being farther told, that when any sound is continuing, as when he is humming a single note or a tune, the glottis is necessarily open, and therefore, that when he chooses to begin pronouncing or droning any simple sound, as the *e* of the English word *berry* (to do which at once no stutterer has difficulty) he thereby opens the glottis, and renders the pronunciation of any other sound easy. If then, in speaking or reading, he joins his words together, as if each phrase formed but one long word, or nearly as a person joins them in singing (and this may be done without its being at all noted as a peculiarity of speech, for all persons do it more or less in their ordinary conversation), the voice never stops, the glottis never closes, and there is of course no stutter. The author has given this explanation or lesson, with an example, to a person, who before would have required half an hour to read a page, but who immediately afterwards read it almost as smoothly as it was possible for any one to do; and who then, on transferring the lesson to the speech, by continued practice and attention, obtained the same facility with respect to it. There are many persons not accounted peculiar in their speech, who in seeking words to express themselves, often rest long between them on the simple sound of *e* mentioned above, saying, for instance, hesitatingly, “*e I e think e you may,*”—the sound never ceasing until the end of the phrase, however long the person may require to pronounce it. Now a stutterer, who to open his glottis at the beginning of a phrase, or to open it in the middle after any interruption, uses such a sound, would not even at first be more remarkable than a drawling speaker,

and he would only require to drawl for a little while, until practice facilitated his command of the other sounds. Although producing the simple sound which we call the *e* of *berry*, or of the French words *de* or *que*, is a means of opening the glottis, which by stutterers is found very generally to answer, there are many cases in which other means are more suitable; as the intelligent preceptor soon discovers.—Were it possible to divide the nerves of the muscles which close the glottis, without at the same time destroying the faculty of producing voice, such an operation would be the most immediate and certain cure of stuttering; and the loss of the faculty of closing the glottis would be of no moment.

“The view given above of the nature of stuttering and its cure, explains the following facts, which to many persons have hitherto appeared extraordinary. Stutterers often can sing well, and without the least interruption,—for the tune being continued, the glottis does not close. Many stutterers also can read poetry well, or any declamatory composition, in which the uninterrupted tone is almost as remarkable as in singing. The cause of stuttering being so simple as above described, one rule given and explained may, in certain cases, instantly cure the defect, however aggravated, as has been observed in not a few instances; and this explains also why an ignorant pretender may occasionally succeed in curing, by giving a rule of which he knows not the reason, and which he cannot modify to the peculiarities of other cases. The same view of the subject explains why the speech of a stutterer has been correctly compared to the escape of liquid from a bottle with a long narrow neck, coming—“either as a hurried gush or not at all:” for when the glottis is once opened, and the stutterer feels that he has the power of utterance, he is glad to hurry out as many words as he can, before the interruption again occurs.

“Should the author’s future experience enable him to simplify or render more complete the views of the nature and cure of stuttering, which he has given above, so as to facilitate the cure in every variety of case, he will not fail to publish his remarks.”

MEDICAL GAZETTE.

Saturday, Dec. 5, 1829.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”—CICERO.

IMPOSING RESTRAINT ON LUNATICS.

WHEN in a recent number we referred to the circumstance of Dr. Burrows having taken active steps on the supposition of an individual being insane, whom he had not seen, we expressed our intention of postponing any comment on the transaction, in compliance with the request of that gentleman, as contained in his explanation to the magistrates. (See Gazette, Nov. 14.) But as we now find that Dr. Burrows does not himself abide by his own proposal, to delay all discussion till the result of a judicial inquiry be known, we hold ourselves absolved from our voluntary offer, and shall proceed to direct the attention of our readers to the principal circumstances of the case.

The inquiry is not a private one, merely involving an individual, nor is it limited to this particular case, but it concerns the profession, and even the public at large, and its discussion may be regarded as comprehending various questions, as to what is lawful and what is expedient in cases of lunacy generally. The point, be it remembered, is not whether Mr. Freeman Anderdon be or be not insane—still less does it consist in any estimate of the “rhapsodies of an obvious madman,” Mr. James Wells, on this occasion—or of the penetration of the gentlemen of the “Home Department,” who were imposed upon by him—or of the taste of the newspapers in giving his letter a place in their columns—but the question is, was Dr. Burrows right or wrong in

directing his attendants to place under restraint an individual whom he had not seen? When the position is thus broadly stated, the common sense of mankind will point at once to the negative, and the accuracy of this decision is, according to our judgment, in no degree impugned by the various exceptions taken against it by Dr. Burrows. For example: it is argued by that gentleman, that "although medical examination of a suspected or alleged lunatic should always precede, where it is possible, his being placed under restraint, many cases must and do occur where that preliminary is wholly impossible." Of course, the case of Mr. Anderdon is held to have been precisely of this description, as the unsettled and wandering habits of that gentleman "presented an insuperable obstacle to an interview with him."

In order to illustrate these circumstances, the following detail is given:—

"Although still a young man, this gentleman has for several years, without any known cause, estranged himself from his highly respectable relations and connexions, and, shunning all human association, took up his abode in a very obscure disreputable part of Lambeth-Marsh. There he resides in a small, miserable, dilapidated house, with broken windows, and a few iron bars across the lower one. It may be inferred, that he has few visitors; for neither the gate of the fore-court, nor house-door, has bell or knocker. He lives a solitary being, without any servant or inmate. His meals he takes at cook-shops, where the lower orders resort. No one knows when he goes out or will return, or can give any account of his movements.

"Let me here ask, how an interview and medical examination was to be obtained within twenty-four hours with such a character?"—*Times*, Nov. 26.

These particulars are sufficient to shew the existence of what Dr. Burrows himself calls "eccentricities;" but they by no means prove insanity; and therefore would not, in any degree,

have justified him in placing Mr. Anderdon under restraint, even had they been the result of his own personal observation—which, however, they were not. But again; supposing that they had been demonstrative of insanity (and no doubt, taken with other evidence, they had appeared satisfactory to Dr. Burrows), still the obvious question remains, by what means the "attendants" were to gain an interview which were not equally open to Dr. Burrows? It might have been difficult,—it would certainly have been troublesome—but it would not have been impossible; and if Dr. Burrows had seen the patient himself, he would, of course, have stood blameless for giving a certificate of his insanity, if he then found him to be a lunatic.

But it does not appear that any attempt was made by Dr. Burrows to see his patient; he seems to have acted implicitly on the representations of others; and this was a great and fatal error—an error which we will not say cannot possibly be explained away; but in what such explanation may consist, is altogether beyond our ingenuity to conjecture. What proceeding, then, is adopted? Let the Doctor speak for himself.

"No alternative being left, instructions were then given to two of my attendants who had been ordered to meet those gentlemen, and they were directed as to the best and safest probable mode of executing their duty. Their directions were, to exercise every delicacy and caution towards Mr. F. Anderdon; to watch his return home; to accost him at his gate before he got in doors; to tell him candidly for what object they came; and to use no violence, but endeavour to persuade him to permit their continuance with him in his own house till the following morning." (*Ibid.*)

It is impossible to imagine a mode of proceeding more entirely injudicious. A gentleman is way-laid near his house, by two men, who are "candidly"

to tell him that he is mad, and that they are going home with him, to remain all night, and to place him under restraint. Had Mr. Anderdon suffered the keepers to go with him, or done otherwise than he did, by giving them in charge to the police, such fact would have been a much stronger proof of his insanity than any that has yet been made public.

The chief point on which we join issue with Dr. Burrows, is as to the propriety of having taken so important a step on the testimony of others. The doctor expressly states, "I hold myself blameless for acting on the evidence adduced by the Messrs. Anderdon, of their brother's malady;" and he argues that, in courts of judicature, the evidence is received of witnesses who have never seen the supposed lunatic. But the cases are not parallel: the utmost extent to which evidence is so received is this,—a medical man is asked, supposing such and such circumstances to be true, do they shew the individual to whom they refer to have been at that time of unsound mind? To wave the incongruity of a private individual supposing that he can ever be warranted in making the same use of evidence as may be done by a court of law, it would be requisite for Dr. Burrows to shew, that, in a judicial investigation, one might be declared a lunatic without the examination of any medical man who had actually seen the patient—for such, to serve his argument, ought to be the usage of the courts.

But farther than all this, in bringing forward a particular instance, where Dr. Munro and he were allowed to give evidence as to the insanity of a person they had not seen, from the representation of others—the Jury paid so little regard to their opinion, that they gave a verdict in opposition to it. This strikes us as a very important feature of the case, and which ought not to have been

omitted when it was thus adduced as a precedent.

But again, Dr. Burrows asks, if a man be seized with furious delirium, or violent mania, "are the parties suffering, or in danger from his fury, to remain passive?" &c. Now this again is forcing a comparison where there is no analogy. If any one be "suffering" from the "fury" of another, he is clearly justified in doing what is required for his own defence, whether the individual by whom the danger is threatened be mad or not; neither, indeed, does it matter a jot which he is. The restraint is here employed, not because the individual is mad, but because there is "danger." The act is founded on a principle analogous to that which allows any one to defend his life against an assassin: it is, to use Dr. Burrows' words, an act of "the parties" who immediately "suffer," not of an indifferent person whom the "danger" does not affect. There certainly are cases of fever with delirium where the physician directs restraint to be imposed, to prevent the patient from injuring himself, but this is never done except by one who attends and sees the individual; and the attempt to force a comparison between this and the case under discussion, shews the weakness of the argument which appeals for support to analogies so distant.

We know it to be illegal, and we hold it to be inexpedient, that any man should be permitted to impose on another the disabilities attached to insanity upon his own individual judgment; that such power should be vested in any one is adverse to the spirit of the English law, and would be highly dangerous to the liberty of the subject. A man may be restrained if he be furious, or attempts to commit suicide, but this is done merely because he is *dangerous* to himself or others; he is not restrained because he is

mad, for it matters not whether his "fury" arise from insanity, delirium, or passion. He is restrained by those who are with him—that is, by those who "suffer." But he cannot be deliberately placed under restraint by a private individual on the principle that he is a madman, however satisfactory to his mind the proofs of insanity may be. We have offered these few remarks upon the subject because it is a general question, the discussion of which, in connexion with the present case, will put medical men on their guard. There is nothing of which the public are more jealous than any measure interfering with personal liberty emanating from a private source, and it is right they should be so. With regard to Dr. Burrows, we are not among those who have either expressed or entertained any of those injurious suspicions to which he alludes; but we think that, however contrary to his usual judgment, he has erred in this particular instance, and that instead of himself repeatedly coming forward to discuss it, he ought to know that it is better to suffer a false step to be overlooked in the general respectability of his character, rather than thus to provoke criticism by attempting to justify it.

THE LANCET *versus* MR. EARLE.

WHEN, a fortnight ago, Mr. Earle addressed a letter to the Editor of the Lancet, we must acknowledge that we questioned the propriety of the step; we felt it to be a condescension to which the latter was not entitled, and which the former could scarcely practise without derogation. Whatever our views in this respect may have been, however, it is quite obvious that the blow to the Lancet has proved one of overwhelming severity. Mr. Earle's letter was evidently the production of an honourable man, writing under strong feelings of indignation and contempt for the

dishonesty and worthlessness of his opponent. He made use of no circumlocution, no equivocation, no shilly-shally half measures—but went straight to the point; charging the Editor with ignorance and malice, and tergiversation, and falsehood. The blows came down quick and heavy, as those of a sledge hammer; there was no parrying them; and accordingly the letter was sent forth without any other comment than a *promise* of future refutation. After a fortnight devoted to deliberation, hesitation, consultation, and mystification, an answer appeared, presenting a remarkable contrast to the original document; no question which this contained was fairly met—no statement contravened—no allegation disproved—no single solitary point refuted. Throughout the writer is obviously twisting and turning, and equivocating. Indeed it is difficult to say whether he produces the strongest impression against his cause, with regard to those circumstances which he leaves unnoticed, or those which he has attempted to answer.

For example, the notorious fact that Mr. Earle had been repeatedly traduced in the pages of the Lancet—that he had been "persecuted for years,"—was placed by that gentleman in contrast with the altered strain subsequently adopted towards him. Wakley denies all this, and says that Mr. Earle has only been able to adduce one instance in which he has been calumniated. *This is false.* Mr. Earle gave one instance as an illustration "*par excellence*,"—one which contained in it references to others; and then adds, that if the readers of the Lancet require more, they may consult his letter in the second number of the Medical Gazette. Yet, while the Editor of the Lancet denies having injured Mr. Earle, he has the inconceivable stupidity to republish one of the strongest examples of his inso-

lence towards that gentleman, consisting of remarks which betray at once all the pertness of ignorance and all the rancour of the deepest malice. The re-insertion of this article at the present period, is an amusing illustration of the extent to which he writhes, under Mr. Earle's castigation. The comments alluded to were professedly the production of the reporter; but Mr. Weekes, who at that time had the misfortune to report for the *Lancet*, publicly denied having penned them, and even stated that he had remonstrated with Wakley on the subject, who replied, that "his conscience was too tender." The truth of this also Wakley now denies, and we expected nothing less than a *written* contradiction from Mr. Weekes to follow; but not at all. The only evidence adduced of Mr. Earle's falsehood, is an admission that clearly proves falsehood indeed—but not with Mr. Earle. It runs thus:—

"We say at once that this is false. Mr. Weekes did not remonstrate with us; he merely expressed a wish that the "reporter" should not be mentioned in connexion with any remarks upon the cases, as it might involve him in difficulties, and that he was particularly anxious not to mix himself up with medical politics."

Is it possible to imagine that any one could be such a blockhead as to deny that Mr. Weekes had "remonstrated," and immediately to add such a paragraph as this? If the above was not a remonstrance, even taking Wakley's own version of it, then pray what was it?

But Wakley says that the comments were written by a reporter, though not by the reporter of the case. If he kept two reporters (one to take cases, and the other to write comments upon them), why did he not say so when Mr. Weekes objected to such remarks being put into his mouth? That Wakley himself wrote the stuff which he then published under the borrowed cloak of Mr.

Weekes, and which he now wishes to shuffle off upon a nonentity of a reporter, is manifest from this—that, in alluding to it, he unwittingly says,

"It was *our* opinion that the application of the trephine could be of no service to a dying man, and this seems to have been a source of unappeasable hostility to the scientific Henry Earle."

In fact, our opinion as to the application of the trephine occurs more than once; and the circumstance is demonstrative that they were our "comments."

Mr. Earle asserts, that Wakley had expressed to several persons (whom he knew were likely to see him, and to repeat what had been said) an opinion of him at variance with that so often given in the *Lancet*; and in corroboration of this statement, he adduces the names of Dr. Armstrong, who attended Wakley's family—Mr. Fay, his friend—and Mr. MacChristie, his reporter. We observed, in speaking of the subject in a former number, that those over whom Wakley had any influence, would be instructed "to eat up their words again;" but, apparently, he has not succeeded in accomplishing this to a satisfactory extent, for he has not favored his readers with the answer he received from any one of these gentlemen to his application. But even taking *his* edition of the story, Mr. Fay does not deny that he made *some* communication to Mr. Earle of the nature alluded to by that gentleman; he merely says, that he was not "authorized" to do so. Mr. Mac Christie tacitly admits all that Mr. Earle said, except that he did not make use of the particular expression of Wakley wishing to make him (*i.e.* Mr. Earle) "reparation."

Dr. Armstrong's answer is the most guarded of all, and amounts to a simple "*non mi recordo*." "Scarcely," says Wakley, "had the maligner's ink dried upon the paper which contained his accusation, ere that excellent physician informed him, that he had no recollec-

tion whatever of having either heard or communicated *any such words.*" On this we must observe, that the ink must have taken marvellously long to dry, as Mr. Earle did not see Dr. Armstrong till after his letter was published. What he then said was, that although aware that he had spoken with Wakley on the subject of Mr. Earle, yet he did not remember any thing of what passed. On this point we take leave to say, that at the time the circumstance took place, a communication was made by Mr. Earle to the Editor of this Journal, informing him, that Wakley had expressed to Dr. Armstrong—precisely the sentiments detailed by Mr. Earle in his letter. This circumstance, for the truth of which we pledge ourselves, is at once the strongest confirmation of Mr. Earle's accuracy, and of the shortness of the Doctor's memory.

Strange as it may appear, these miserable attempts to take exceptions to particular words and phrases, instead of disproving the spirit of the communication, is all the attempt made to answer any part of Mr. Earle's letter; while all the chief points are left wholly unnoticed. For example:—The allegation of Wakley having at one time habitually libelled Mr. Earle, and subsequently adopted a tone entirely different—*is not answered.* The allegation of his having published and advised the pupils to attend the lectures which he now attempts to ridicule—*is not answered.* The allegation of absurdity in asserting that his gravest statements were made in irony—*is not answered.* The allegation that the reporter of the Lancet had formally applied to Mr. Earle for notes of his lectures—*is not answered.* The allegation that an application was made to Mr. Earle, and refused, for the MS. of a particular lecture, the non-publication of which, Wakley says, was the cause of offence—*is not answered.* The allegation that Wakley's abuse of

Mr. Earle originated not in any thing connected with the discharge of his duty, but solely an idea that he had contributed to a fund for putting down the Lancet—*is not answered.*

The Editor of the Lancet, apparently aware how totally he has failed in his answer, introduces a good deal of vapouring about his "feelings"—his "satisfaction"—his "triumph"—his "pride"—his "exultation"—and sundry other grandiloquent words, winds up the climax of absurdity with an appeal to the "rectitude" of his conduct! As to this last we really cannot speak, never having heard of it before; but if he has one particle of those "feelings" to which he alludes, we pity him when he looks upon the part he has enacted on this occasion—that of a braggart, who talks big while he thinks his challenge will not be accepted, and then sneaks off with a few retiring flourishes—detected, baffled, and exposed.

THE KING'S MEDAL.

THE King's "first medal" has been presented, by the Council of the Royal Society, to Mr. Bell, on account of his "profound researches in the nervous system." The first medal was last year presented to Dr. Prout. Thus have two members of our profession obtained the highest honors in science during two successive seasons. We are proud of this, as reflecting lustre on medicine; but we cannot help asking, would it not be a more substantial proof of the Society's approbation if the medal consisted in something more than the mere name? At the end of three years has Sir Thomas Lawrence not been able to invent a device worthy of so noble a purpose as the patronage of royalty extended to science? Our readers will scarcely believe that no "medal" is yet in existence!

LONDON UNIVERSITY.

We understand that the Council of the London University have abandoned all intention of attaching an hospital to that institution.

HOSPITAL REPORTS.

MIDDLESEX HOSPITAL.

Case of fatal Extravasation of Blood into the Cavity of the Pleura.

AUGUST 25, 1829.—William Murphy, a shoe-maker, aged 21, was admitted into the Middlesex Hospital, under the care of Dr. Francis Hawkins. He complained of having been ill three days, with pain in his left side and a dry cough. His pulse was somewhat sharp, but not decidedly hard, nor full, nor frequent. His countenance was pale and unhealthy, and he stated that, two years before, his leg had been amputated for a white swelling.

He was ordered to be bled to the amount of twelve ounces; to have a blister applied to his left side; to take Hydr. Submur. gr. iv. Pulv. Antimon. gr. vj. and Pulv. Ipecac. o. gr. v. at night; and a draught containing Aceti Scillæ, f. 3ss. and Magnæ Sulphat. 3ss. three times a-day.

Aug. 26.—Very little blood had been obtained from the arm, and it had flowed slowly. It did not appear to be at all inflamed; but the bleeding, he stated, gave him great relief. His pulse was not so sharp, but his skin was hot. His bowels had not been opened.

He was directed to take a Senna draught immediately, and Pil. Scillæ c. gr. v. Opii, gr. ss. every night at bed-time.

After this he appeared to revive, and, to a certain extent, to recover strength; and he complained very little of cough. But his countenance wore the same pallid and unhealthy appearance as before, and he continued subject to occasional returns of pain in his left side, which were relieved several times by blisters and expectorant draughts. He was unable to lie on the right side without uneasiness. Over the whole of the left side there was dulness of sound on percussion, and the respiration was inaudible through the stethoscope; indications which were not observable on the opposite side. He was subject also to nocturnal perspirations, which were checked by small doses of sulphuric acid, with syrup of poppies or tincture of opium, taken at bed-time.

About the beginning of October, he began

to suffer from pain in the left shoulder, which continued to recur at intervals afterwards.

On the 16th of October, it was observed that the left side of his chest was considerably enlarged, and the ribs on that side less moveable than on the other. Although there was little or no protrusion of the parietes of the chest in the intercostal spaces, yet a slight fluctuation could be perceived in the upper part of the chest, between the anterior and posterior sides, on pressing from behind forwards. There was also a slight puffiness of the pectoral muscle, and of the left side of the neck and face. There was no urgent dyspnoea present, nor had the pain and uneasiness in the side increased.

With the hope of promoting absorption, he was ordered to rub over the chest the unguent. antim. tart., which was subsequently changed for liniment. hydrarg., and to take squill and pil. hydrarg., digitalis, and other diuretics.

On the 19th of October the difficulty of breathing had not become greater, nor did it at any time in the subsequent progress of the case become urgent or distressing. The slight fluctuation before perceived in the chest, was now less distinct. The heart's action was felt strongly and solely on the right side of the sternum.

On the 21st, the chief pain of which the patient complained was beneath the inferior edge of the scapula. There was very little cough, and no expectoration.

On the 22d, it was observed that the right side had the appearance of bulging out almost as much as the other; but, on actual measurement a short time afterwards, the circumference of the left side was found to exceed that of the other by an inch. After this, from the increasing weakness and sufferings of the patient, it became nearly impossible to measure his chest.

Oct. 26th.—There was more cough, but the difficulty of breathing was considerably relieved. The patient's bowels, which had hitherto been rather confined than otherwise, were at this time much relaxed.

27th.—The purging still continued, and the urine, which had long been remarkably thick and ropy, and had deposited a vast quantity of red sand, in spite of the alkaline medicines which he was taking, now appeared clear; but it frequently afterwards exhibited the same blood-red appearance as before.

The diarrhoea, which was uncontrollable by opiates, absorbents, and astringents, continued, with little intermission, greatly to reduce the patient's strength. Latterly, there was an increase of cough, and he expectorated curdled mucus, nearly resembling what is considered to be tuberculous matter. The left side had now lost all appearance of enlargement, the ribs of that side, although immovable, being no longer elevated. But

the heart's pulsations were still confined to the right side.

On the 10th of November he died, his strength being apparently exhausted gradually.

On the following day the body was examined.

The left side of the chest yielded, when struck, as little sound as a piece of marble. The right side yielded, for the most part, a hollow sound. On sawing through the ribs on the left side, a considerable quantity of a brownish serum gushed out; and on opening the chest, a mass of substance was disclosed, having at first the appearance of a fungoid growth, which occupied the whole of the left side of the chest, and extended itself even on the other side of the spine, having thrust the heart entirely to the right side of the sternum. At first, it was surmised that the whole of the lungs of the left side had been converted into a fungoid substance, but from the appearance of the mass when taken out, (resembling, when cut into, a mass of coagulated blood in different stages of alteration, disposed partly in layers, and partly in a cellular manner, and not altogether unlike the clot of an aneurism,) as well as from the other circumstances of the case, it was suggested by one of the by-standers (Dr. Harrison), that it must have been blood effused into the cavity of the pleura, a supposition which further examination verified, for the lungs of the left side were found condensed into a very small space against the spine, and the pleura pulmonalis, covering them, was entire, to the external surface of which this coagulum slightly adhered.

Upon examining further the parietes of the chest, a sort of rough cavity was felt in two of the ribs, (about the fifth and sixth.) They were taken out, and the lower margin of each, on the inner side, was found to be destroyed for the space of about an inch near their angle. The intercostal artery belonging to one of them was entire, but under the other, which was most decayed, it was wholly wanting: it had in that part been entirely destroyed. The external surface of these ribs was sound, nor could any trace of fracture be discovered.

The condensed lungs of the left side appeared upon incision to be filled with small tubercles; but this appearance arose from the contracted state of the bronchial tubes, out of which thick mucus could be squeezed, similar to that which had latterly been expectorated.

The lungs of the right side were healthy, except that the bronchial tubes in their upper part felt harder and more cartilaginous than usual, in some places almost bony.

The heart had its right auricle much enlarged; in other respects it was sound in structure.

The liver was immensely gorged with

dark blood, but its internal structure did not appear to have undergone any alteration.

The mucous lining of the small intestines was remarkably attenuated. Although no elevated ulcers were observed, in two places there was found a small round perforation quite through the coats of the intestine, yet its contents did not appear to have passed into the cavity of the abdomen, nor did the peritoneum appear to be inflamed.

No other morbid appearances were discovered.

From the previous history and general appearance of the patient, this case had been referred to the common class of tubercular phthisis, complicated, as it sometimes is, with inflammation of the pleura; an explanation with which many of the symptoms appeared to agree sufficiently well. In fact, when many of the symptoms of a disorder which occurs very frequently are present, the chances are so much in favor of an individual case being of the same nature, that we are often led to consider it as such in a somewhat hasty and indolent manner. The examination of this case, which disclosed the unusual circumstance of long-continued hæmorrhage from an intercostal artery, may serve to show that we can never be too precise and particular in investigating the pathology of a case which exhibits any deviation from the usual combination of symptoms, either through the absence of some or substitution of others.

EDINBURGH ROYAL INFIRMARY.

Lithotomy.

JAMES TAIT, æt. 16, admitted under the care of Mr. Lizars, July 31st.

Last winter he began to suffer from micturition: his urine passed sometimes involuntarily, and in a small stream, attended with uneasiness in the hypogastrium. In the beginning of the summer he felt pain at the extremity of the penis during and after making water, and also in the loins and perineum, occasionally so severe as to prevent him from sitting. About a month ago he passed several small particles of uric acid. Bowels constipated; general health good.

A calculus is distinctly felt by the introduction of the sound. His urine is frequently bloody, and he complains of constant and severe pain in the loins, preventing sleep. His bowels were freely opened in the evening by castor oil.

August 1.—To-day the lateral operation of lithotomy was performed by Mr. Lizars, and a small stone was readily extracted with the scoop. A flexible gum tube was placed in the wound. After the patient had been put to bed, hæmorrhage occurred, but was

arrested by ligature, and the wound stuffed with lint.

4th.—Doing well; bowels rather constipated. Ordered *Ol. Ricini* ℥j. Urine passes by the wound.

10th.—The urine passes naturally; the wound is cicatrising, and the general health of the patient is good.

Sept. 20.—Had acute pain during the night in the left lumbar region. In the morning retention of urine occurred, the urethra being obstructed by a calculus lodged about half an inch posterior to the glans penis. The stone having been pushed forwards, orifice of the urethra was enlarged with a bistoury, and a mulberry calculus of the size of a horse-bean was extracted with some difficulty.

22d.—Still complains of severe pain in the region of the left kidney. A seton was applied in left lumbar region.

23d.—Pain in loins much diminished.

26th.—To-day the patient was sounded, but no calculus could be discovered. He has now slight incontinence of urine, but is otherwise free of complaint.

Hernia Cerebri.

Edmund Young, æt. 18, admitted under the care of Mr. Liston, Sept. 10.

Last night received a kick on the forehead from a horse; he remained perfectly sensible, and did not fall to the ground. Shortly after he was seized with vomiting, which has recurred at intervals. Pulse regular, but feeble; pupils dilated. On the centre of the forehead there is a triangular wound, which extends to the root of the nose: on introducing the finger, the os frontis is found fractured, the lower portion being comminuted and depressed. The trephine was applied, and several detached portions were removed, with some difficulty, from beneath the undressed portion of the bone. A spicula had lacerated the dura mater, and penetrated the substance of the brain to the extent of half an inch; on removing it, a small portion of cerebral matter escaped. The fracture extended apparently in the direction of the right orbit.

Mr. Liston's prognosis was very unfavourable.

In the afternoon the patient's pulse was 64, of good strength, and the pain in the wound had slightly increased. He was bled to ℥xiv.

Rx Tart. Antimonii gr. ii.

Sulph. Magnesiae ℥iiss.

Aquæ ℥xx. ℥j. every hour.

Sept. 11.—Passed a good night. Complains of little pain, but there is a slight swelling of the scalp around the wound. Had an enema, which procured three copious stools; pulse 90, skin of moderate temperature, tongue foul, some thirst.

V. S. ad ℥xiv.

12th.—The pain in the head and the puffiness of the scalp have somewhat increased; skin hot, pulse 90.

V. S. ad ℥xii.

15th.—The pain in the head is more severe. Pulse 96, bowels open. Healthy discharge from wound.

16th.—An abscess having formed over the lachrymal sac, was opened, and a quantity of pus evacuated.

18th.—Was very restless last night; the scalp is tumid, and tender on pressure; pulse 90. The original wound was enlarged, and a considerable quantity of pus escaped. ℥xx. of blood were abstracted; blood buffed and cupped. He afterwards became much calmer, and the swelling and pain decreased. Pulse 110.

19th.—On left temple there was considerable tension and pain of scalp, which was relieved by an incision.

20th.—There is some appearance of fungus cerebri, and a portion of brain seems to have sloughed. An incision was made into a swelling over the right temporal muscle, and ℥viii. of blood allowed to flow.

21st.—Several portions of brain have been discharged; pulse 100, and intermitting; profuse perspiration; bowels open. Had ℥xx. of liquor Sedativus, after which he became more composed.

22d.—The patient is delirious, and a hernia cerebri protrudes, of a sloughy appearance and considerable size. Pulse 142, skin dry, pupils natural. Soon after the visit he became comatose, and died early in the morning of the 23d.

A moderate and uniform degree of pressure had been constantly applied to the wound, by folded lint and a bandage.

Dissection.—The integuments and pericranium surrounding the aperture in the frontal bone were much thickened, and infiltrated with pus and serum. The dura mater, at the wound, was of a sloughy appearance. There was great effusion of purulent matter under dura mater investing the right hemisphere of brain; the corresponding tunica arachnoidea was thickened and opaque, and between it and the pia mater there was considerable deposition of lymph and pus. The fungus was collapsed, of a dark colour, soft consistence, and connected with the anterior lobes; the surrounding cerebral matter was much softened, and mixed with pus. The fracture extended through the orbital plate of the right os frontis, over which lay two small spiculæ of bone; and a similar fragment was situated over the right optic nerve.

WESTMINSTER HOSPITAL.

Diseased Hand.—Amputation.

Geo. Cross, æt. 41, admitted Nov. 17, 1829,

under Sir A. Carlisle. This is nearly a similar case to the one in our last Number. Twenty months ago, in putting up some shutters, he was about to place the bar to secure them; some one who held the other end turned it rather suddenly round, and gave his wrist a slight twist. He attributes the whole of the subsequent disease to this cause, and he does not recollect to have observed that he was much out of health at the time. He took no notice of the sprain for a day or two, when he observed that the wrist was slightly swelled, and he experienced pain, particularly when he was warm in bed. He applied to a chemist, who gave him a camphor liniment. The swelling increased, and the pain continued unabated. He then applied to a surgeon, who ordered him a dozen leeches, and he says he lost the entire use of his hand immediately after their application—for previous to that he could move it about a little and use his fingers, but from that time felt them quite useless. Leeches were repeated frequently at intervals, and after a time a succession of blisters was ordered. The hand remained, as nearly as he can describe, in precisely the same state—equally swelled, painful, and hot. It was then (sixteen months back) opened on the back of the hand, and a small quantity of matter escaped. He was ordered to foment and poultice it, which he has continued doing ever since. Six months back, several openings formed both on the back of the hand and towards the palm and front of the wrist. Several incisions have been made from time to time, by the surgeons attending him. He says no bone or ligament has ever come away to his knowledge.

His hand is at present extended, without any power of closing it, or bending the wrist. There are several openings at different points, which discharge. The bones of the carpus seem unconfined by ligaments. The pain is less than it has been, but his hand is quite useless, and a constant source of irritation and ill health. He is a servant, married, and says he has lived a regular and temperate life, generally enjoying good health. His pulse is extremely feeble, 65 in the minute; tongue pale and clean; bowels slightly confined, and his figure rather emaciated. His appetite has been very bad ever since the accident until within the last month or six weeks.

R Magn. Carb. 3j.

Pulv. Rhei. grs. xv. ft. pulv. v. m. s.

Nov. 20th.—After a few observations by Sir Anthony Carlisle on the nature of the case, the patient was brought into the theatre, and the amputation performed by a circular incision, about four inches above the extremities of the radius and ulna. The radial and ulnar arteries were secured, as also a branch of the profunda. The edges

of the flaps were brought accurately together, and the usual dressings applied.

On making an incision down the wrist and hand into the joint, the whole of the bones of the carpus, the extremities of the radius and ulna, and metacarpal bones, were entirely denuded of cartilage; and all the carpal bones more or less absorbed, presenting sharp and ragged surfaces. The metacarpal bones, in their length, were also more or less diseased, with fungous-looking excrescences growing up from between them, and upon the upper surfaces.

Diseased Penis—Amputation.

John Mills, æt. 55, admitted Nov. 7th, 1829, under Sir Anthony Carlisle. This patient refers the commencement of his disease to about fifteen years back, when he felt slight pain at the extremity of the penis, and shortly afterwards experienced difficulty in drawing back the prepuce. He was living at this time an irregular life; the pain and inflammation continued, and he found it quite impossible to draw back the skin, nor has he ever been able to do so since. He has not, however, been prevented following his occupation (as a gentleman's servant) until November 1828, when he was admitted into this hospital, under Sir G. Tuthill, for asthma; while he was in he was transferred to Sir A. Carlisle.

The treatment since his being transferred has consisted in the employment of different lotions; carrying the dressings down as far as possible; endeavouring to separate the glans from the prepuce; and preventing the latter from closing in, to which there was evidently great disposition. The prepuce was also freed several times by incisions, but with little benefit. It was found impossible to keep the glans exposed. In making the incisions the prepuce next the gland was found quite cartilaginous.

A consultation having been held, it was determined to amputate the penis, which was done on Saturday, November the 14th, by Mr. Harding. The skin being drawn back by an assistant, he began at the upper surface, about an inch from the pubes, and carried the scalpel perpendicularly down, making one clean incision. Three arteries were secured; the stump dressed, and the man put to bed.

Nov. 15th.—He complains of great smarting pain on making water, but is otherwise tolerably easy.

Nov. 17th.—Granulations are appearing on the surface, and the stump seems to be gradually healing over.

Nov. 20.—The stump is looking well, and with the exception of a slight diarrhoea, feels tolerably well in health.

Medicine and the Collateral Sciences.

SATURDAY, DECEMBER 12, 1829.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

LECTURE XL

Suppuration—Abscess—its Treatment.

SUPPURATION, gentlemen, is the formation of a fluid, which is called *pus*; it is one of the effects of inflammation, and therefore whenever we find *pus*, we are certain that there either is, or has been, inflammation in the part. *Pus* is a whitish or yellowish fluid, varying in consistency from that of the thickest cream to that of water; and it is found, on microscopical examination, to consist of globules floating in a thin fluid, in this respect, bearing some analogy to the blood.

The differences in the consistence and other properties of *pus* depend chiefly on the nature and degree of the inflammation, and on the structure of the part in which it is formed. *Pus* is sometimes thick and homogeneous—sometimes it is flaky or clotted—sometimes it is serous or watery—sometimes it is viscid or slimy.

I have spoken to you of suppuration as one of the effects of inflammation; but the formation of *pus* is not confined to the circumstances which were then explained or alluded to. *Pus* may be formed on the surface of the skin—for example, after the application of a blister—it is formed on the surface of an inflamed mucous or serous membrane—on that of an inflamed synovial membrane—on the surface of wounds of any of the soft parts, or of ulcers—and it is formed in consequence of inflammation in the interior, or substance of various organs. When *pus* is thus formed, the collection of fluid which it constitutes is called an *abscess*. An abscess, therefore, is a purulent collection in the interior of any part of

the body, excepting, however, the regular or normal cavities; for when *pus*, or any kind of fluid is formed in them, we call it *effusion*, not abscess.

Inflammation, as I have already informed you, differs greatly, in different instances, in the violence of its symptoms, and in the rapidity of its progress—sometimes going quickly through its course, and at others occupying a long time. The formation of matter in suppuration partakes of the same variety of character which is observed in the inflammation that produces it. You may have *pus* completely formed in an abscess, and fully developed in the course of a short time—two or three days for instance; or you may have the collection increasing and remaining in the part, without coming to an end for several weeks or months; or perhaps even years. We might, therefore, designate suppuration, as we do inflammation, by the terms *acute* and *chronic*; and, in fact, we speak constantly of *chronic* abscess, though we do not use the term *acute*, but *phlegmonous* abscess, to denote those collections that are produced by the more violent and rapid forms of inflammation.

I shall first speak of suppuration as it occurs in a *phlegmonous* abscess. When the inflammation has proceeded to a considerable degree, matter is deposited in the centre of the inflamed part. The inflamed textures, as I have already mentioned, become in some measure softened, or at least the power of cohesion is lessened by the process of inflammation. In the centre of the inflamed part *pus* is formed, and, in fact, portions of the texture lose their cohesion, and may be said to be broken down. When this effect is produced, there is an effusion from the inflamed vessels, which is of rather a thin or serous appearance, and somewhat of a bloody colour. When I say the texture is broken down, I do not allude to a mechanical process, but to a change in the condition of the textures of a part, the result of violent action. We now begin to perceive white spots of matter disseminated here and there

in the seat of the highest action, and these soon unite together, so as to form one cavity. The cavity which is thus formed enlarges, it increases in size, by pushing aside the cellular substance and surrounding soft parts, which yield more or less according to their nature. Now such of those parts as are firmer make resistance, and do not give way—namely, blood vessels, nerves, and tendons. These form elevations or ridges on the side of the abscess, and sometimes they constitute a sort of fibrous crossing, from one side of the cavity to the other. When we examine the part, it is found soft and pulpy, and presents a greyish appearance. If we take the handle of a knife, we can scrape off a pulpy grey substance, which is generally supposed to consist of coagulable lymph, effused in consequence of the inflammatory action. It appears, indeed, not to be organised, although it closely adheres to the surface of the part. When we have thus scraped off this covering, we find that the interior of the abscess presents the appearance of a dense texture, that has been compared, and not inaptly, to that of a mucous membrane: it is reddish in colour, firm and compact in structure, and tolerably uniform. This kind of membranous structure constitutes what we call technically the *cyst*—that is, the walls and sides of an abscess; in fact, if the contents were taken out, the abscess would then present a bag or cyst. The internal surface of this cyst is not connected with the matter which the abscess contains. The external surface of the surrounding cellular membrane, and the other soft parts in which the abscess is formed, are closely adherent, being condensed and rendered preternaturally firm in texture by the inflammatory process. This condensation extends to a greater or less distance round the abscess, till it gradually passes into the natural texture of the surrounding parts. In an earlier stage of the formation of pus, there is a considerable portion of this condensed or hardened substance surrounding the cyst; but in proportion as the collection of pus increases, the surrounding hardness becomes less in extent. The *parietes* or walls, or cyst of the abscess, is obviously occasioned by the consolidation of the cellular texture in the part, in consequence of the effusion of lymph into it. The inflammatory disturbance, which excites suppuration in the centre of the inflamed part, produces the effect of interstitial deposition in the circumference. In the language of Mr. Hunter, “the inflammation in the centre is suppurative inflammation, and in the surrounding parts it is adhesive inflammation.” The cyst thus formed constitutes a natural frame, which contains the pus, and separates it from the surrounding parts. If it were not for this, the pus would be disseminated in the cellular substance of the part in which it is deposited;

and, like serum in anasarca, it might extend over the whole of the limb.

The pus which is contained in an abscess formed under these circumstances is thick, homogeneous, and generally of a whitish colour;—when I say *thick*, I mean it is equal in thickness to the thickest cream, and sometimes so thick that it comes to the consistency of a soft solid, such as butter, and, generally speaking, the higher the degree of inflammation, the thicker is the pus produced by it. This is the kind of pus which pathologists call *good laudable pus*—that is, it is a kind of purulent secretion which is produced by a high degree of inflammation occurring in an healthy individual. This, no doubt, is the reason that has given rise to the term *laudable pus*. The pus thus formed is found to be heavier than water—that is, if it is received into a vessel of water it sinks to the bottom; and this circumstance has been considered as a criterion for judging between pus and mucus. Much pains has been taken to point out the difference between these two; for, under certain circumstances, it becomes a matter of importance to determine whether a certain secretion be the product of inflammation—pus, or whether it be a mucous secretion. Unfortunately, however, no very clear criterion has yet been adduced. Between the purulent fluid that has been found in a phlegmonous abscess, and the ordinary secretion from the various mucous membranes, there are such obvious differences, that we are not in any want of a minute criterion; but I believe no criterion can be depended on for distinguishing fluid that is the product of an inflamed mucous membrane, and that which is the product of suppuration. It has been remarked that mucous fluid generally floats in water, instead of sinking in it; but this is by no means universal. Mucus will sometimes sink in the chamber-pot in urine, although urine is of greater specific gravity than water. Mucus is a ropy fluid, while pus does not present that character. But there are intermediate gradations by which the natural viscosity of mucus in a healthy state passes into a condition which bears a close resemblance to pus.

Heretofore an opinion was held that pus is produced by the breaking down or melting of the natural textures of a part; this idea no doubt arose from a cavity being found in a part where suppuration has taken place,—a notion being entertained that the pus consisted of the natural texture that previously filled the cavity, reduced by some strange process into the form of pus. Again, it has been supposed that pus is formed by some putrefaction or fermentation of the fluids of the part. It has further been contended that pus can only be formed in consequence of the process of ulceration. Thus when pus has proceeded from any of the

mucous cavities by their external outlets, it has been supposed that ulceration existed in them. All these notions have vanished in proportion as correct physiology has advanced, and as examinations have been instituted after death in cases of inflammation. Although considerable controversies existed some years ago on this point, these are now completely settled. It has been supposed again, that pus arises from a deposition in a part, and that it gradually undergoes a change that converts it into pus. Now the truth is, that the sides of an abscess secrete pus, and there is no passing through successive gradations—there is no elaboration of fluid to bring it into pus, except so far as respects the commencement of the process, for there is a breaking down of the textures of the part in the first instance to form the cavity in which the pus is afterwards to be contained. The fluid first deposited has a serous, and sometimes a bloody character, though afterwards we find in the same part a secretion, having all the characteristics that belong to pus. This, however, only applies to the first commencement of the process. The same may be said in cases of inflammation of the cutis or of mucous membrane. We do not find that the pus deposited at first is perfect, but that a serous fluid is poured out from the skin, and this is changed for the fluid that constitutes pus. There is a similar gradual change from the colourless viscid mucous secretion belonging to the mucous membrane, to the thick yellow purulent matter which we sometimes see in high inflammation of these parts. We usually see appearances that lead us to suppose there is something like a giving way of the textures of the part in which suppuration takes place. Some time ago we had a patient here that was sent from the fever hospital, in whom a considerable abscess had formed on the side of the hip. I made a puncture, and let out a fluid that appeared to me pretty much like oil; and I found, when it was received into a vessel, that it consisted of pus and oil floating in it. Seeing it came out together with the pus, I have no doubt it was the oily matter connected with the adipose structure in which suppuration took place. Sometimes there is an admixture of pus with bile. This is the case in hepatitis, where the parts are broken down, and such pus has a kind of yellow hue, derived from the colour of the secretion of the liver.

The surface of an abscess secretes the pus which it contains; and it is also capable of absorbing or taking up again the fluid it has deposited. It has a secreting and absorbing surface; and hence we may regard the cyst of the abscess as a kind of new organic deposition in the part.

With respect to the symptoms of suppuration: when inflammation has been of a violent kind; when it is rapid in its

progress, and there is throbbing pain, we may expect that suppuration will occur. The actual formation of matter in the part is characterized by a cessation of local pain; it becomes less severe, and frequently seems to stop altogether. There is soon, however, a kind of dull aching sensation; there is a feeling of tension; and when the matter is forming, there generally is throbbing. A kind of pulsation synchronous, with that of the heart, takes place in the organ immediately before the formation of matter, and during the time it is forming. At first it is common to have shivering; and this has been in general regarded as one of the most certain signs of the formation of matter in the abscess. Now the truth is, the formation of matter takes place where there are no rigors; and rigors occur where there is no suppuration. Rigors, too, occur in most of the spontaneous inflammations of the body. The most unequivocal evidence, however, of matter having formed in a part, is the soft feel which its presence communicates to the hand of the examiner. When you come to feel the part you are sensible that a fluid exists in it; and if you apply two fingers, making pressure with them alternately, you find that the fluid can be pushed from one part to another, what we call imparting the sense of *fluctuation*. It is often of consequence to ascertain whether there be matter or not; and hence we frequently examine the part carefully to ascertain this point. It is difficult to describe this sensation, and I do not know that it can be done: you will, therefore, only be able to understand the kind of feeling that is communicated by the presence of matter by actually examining the parts where suppuration has taken place. When matter has formed at some depth from the surface, of course it becomes difficult to ascertain the fact. When you examine a part in which the point is very doubtful, it is perhaps not so well to use the fingers of both hands, and press alternately with them, because you often produce a kind of fluctuation where no suppuration has taken place; but if you place one hand upon the part, and then make slight pressure with the other, and if you feel against the hand a resistance, or kind of impulse, you may pretty safely conclude that matter is formed in the part.

When suppuration has taken place, the cavity of the abscess, as I have said, extends itself in all directions, becoming larger and larger. In this extension we observe, of course, that it enlarges most readily in those directions in which the resistance is less. Generally speaking, therefore, the cavity of the abscess enlarges towards the external surface of the body, because in that direction there is less resistance to its full development: or it tends to increase towards the surface of any of the mucous cavities or canals of the body.

This progress of the abscess, however, towards the external surface, or towards any of the natural outlets, does not depend simply upon the circumstance of there being less resistance, for the abscess will sometimes take either of these courses, even although there should be much less resistance to its progress in other directions. Suppose an abscess to take place in the parietes of the abdomen or chest, and to be seated near the surface of the serous membrane lining the cavity, the abscess will, nevertheless, in a majority of instances, pass through the parietes externally, although it may have been covered internally by a thin surface. However deep an abscess may be formed, and however it may be covered externally by unyielding parts, the natural tendency of the process is to remove the parts that are seated between the collection and the skin, and, consequently, to bring the matter to discharge externally, either on the surface of the body or into some of its mucous outlets.

In the progress of the abscess towards the external surface, there is a gradual removal of the parts which intervene between the collection and the surface; here, therefore, a new process is required. So far as we have hitherto seen, we have the inflammation producing the deposition of pus in the cavity of the abscess, and consolidating the textures that environ it, forming a barrier, and insulating it from the surrounding parts. But another, and quite a different process, now becomes necessary. To bring the matter to the external surface, you must have a regular removal by absorption of the parts that intervene between them. The external surface of the abscess becomes thinner and thinner, and the feeling of the fluid becomes more and more obvious. The fluctuation, as it is technically called, is more easily perceived. As this process goes on, the swelling in the circumference of the abscess becomes reddened; at the same time, the central part, where the sense of fluctuation is produced, swells more considerably, and rises prominently on the surface. The prominence often assumes a pointed form, and we are enabled to see the spot at which the abscess will break. This is that part of the process which is technically called the *pointing* of an abscess. When the matter approaches the skin, this becomes red, tense, and shining. As the skin becomes thinner and thinner, this redness becomes deeper in tint; it assumes a livid hue, until at length the skin ulcerates, and then the matter escapes at the opening. If the cuticle covering the ulcer at the part be thick, as in the palm of the hand, you find the matter will elevate the cuticle extensively until it gives way, and the matter is evacuated. A certain quantity of the contents of the ab-

cess escapes at the aperture that is thus made; and although the opening formed by the ulceration of the skin is in general a small one, so much of the matter escapes as to relieve the tension of the part, and the patient is considerably easier than before. The sides of the abscess contract in consequence of this abstraction of a portion of their contents. When a fresh quantity of pus has been secreted, it again flows through the opening, and the size of the aperture becomes more considerable by the extension of the ulcerative process. The opening soon becomes large enough to allow the contents of the abscess to drain away; the sides then gradually contract or collapse, the part heals over, and thus a natural cure is effected. Sometimes, however, where motion is constantly taking place, and also in some instances, where we do not observe the cause, the cavity of the abscess does not become completely obliterated; it is reduced to a small extent, but still there is an external opening from which matter escapes. We find the external opening leads into a small tube, of various extent in different instances; and that small tube, which is the remains of the abscess, and the external opening through which its matter is discharged, constitutes what is technically termed *fistula*, meaning a tube or pipe.

We have next to consider the *treatment* of the kind of abscess I have now described. I have mentioned that the sides of the abscess are capable of absorbing as well as secreting pus; we may, therefore, conclude, that if the process of inflammation could be completely stopped, the pus contained in the abscess might be taken up by the absorbents. Thus the natural cure of the abscess would be effected without the matter being discharged at all. In this way abscesses are sometimes cured without either bursting or being opened artificially. It is, however, not a frequent mode of cure; and certainly, as a *general* rule, we may say that when matter is formed in a part it must either be discharged by the natural process I have now mentioned, or by surgical operation. I think the most frequent examples of cure of abscess by absorption are afforded by venereal buboes. There is a young woman in Magdalen ward in whom a very considerable collection of matter in a venereal bubo has been disposed of in the way I have mentioned—namely, by absorption. She came into the ward with a venereal sore, and the labium pudendi in a state of suppuration; the skin was of a bright red, and very tense. The bubo might have contained an ounce of matter; and, in fact, the skin was so red and tense that I thought it should be opened. Some circumstances led me to postpone it; and when I saw the patient at the next visit, it did not appear to me so large; she felt easier, and I did not then open it. On the

subsequent visit it appeared that the bubo was still farther diminished in size; the redness had gradually gone of; the softness and the fluctuation had become less considerable, and the matter was now entirely removed. Thus a collection of a considerable size had been disposed of in the way alluded to. The treatment has simply been keeping the patient quiet, applying a poultice over the part, and giving mercury in moderate doses.

The dispersion of abscess in this way does not take place often enough to lead us to found on it any general mode of treatment. With reference to that particular object, it may be said that the mere occurrence of suppuration is not a sufficient reason for giving up the employment of antiphlogistic means, which have been previously used to reduce the inflammation. There is often a great deal of inflammation existing, and a great deal of redness and hardness, although no matter is formed in the part; and we often may continue leeching, with the general means that are calculated to lessen the inflammation, although we already see matter formed at one point; and such a course of proceeding will be likely to favour the dispersion of the abscess by absorption. When matter has formed, we may leave it generally to itself, avoiding all those causes that would be likely to disturb the natural process. Thus we should keep the part at rest, and covered with a soft poultice; place the patient on low diet, and pay attention to the general health; and with this assistance we may allow the abscess to go through its own course. It is, however, frequently found necessary to discharge the matter by an artificial opening, and different modes have been taken to accomplish this object. Abscesses have been opened by seton, by caustic, by puncture, or by incision. In discharging abscess by a seton, this has been introduced by means of a steel needle carried through the sides of the abscess, at one point of the cavity, till it has been brought out at the opposite extremity, and the thread has been left in. The opening thus made allows the matter gradually to find its way out by the side of the seton. With respect to a phlegmonous abscess, this plan is inadmissible on account of the irritation it would produce; and, in fact, it is so destitute of recommendation that it is now abandoned. In the mode of opening an abscess by caustic, the prominent part, the thin portion of the skin, has been rubbed with pure potash, and the slough, thus formed, has been allowed to separate, the matter falling out when the slough has been detached; or sometimes, when the slough has been formed a day or two, an opening has been made with a knife, and the matter has thus been let out. This is a kind of proceeding which is not generally applicable; and perhaps the only case in which caustic can be advantageously used is in bubo, where the

skin has become very thin; where there has been a considerable separation of the subjacent parts, so that they are likely to form a slough. I should have mentioned, in speaking of the nature and formation of abscesses, that when the skin has been rendered thin, it not unfrequently happens that the part sloughs, and the matter escapes in consequence of this natural process.

Generally, when we attempt to discharge the abscess artificially, we should do so by the direct means of a puncture, or incision—that is, by making an opening in the collection with a cutting instrument. The common broad lancet has been used for this purpose, but this is not the most convenient—and I think the best instrument is the straight double-edged bistoury. It punctures very easily, on account of the sharp point; and when you have carried it into the abscess, you can easily extend the opening to any size you wish. With this instrument you can easily puncture the abscess equal to the breadth of the blade; and if you wish to have the opening large, you can extend the incision by a slight motion of the hand, as far as you please. If the skin has become firm, then you will generally find it necessary to make a slight incision, in order to let out the matter, and you will find the opening but little bigger than if you make a small puncture. It is not necessary to make a large cut, as some gentlemen do; and still less is it proper to introduce the finger into the cavity of the abscess. I remember seeing a surgeon make an opening, and introduce his finger and turn it round several times, inflicting great torture on the patient, for the purpose of removing the core. In fact, discharge in any artificial way from an abscess, is apt to produce an accession of inflammation in the part; and if, in addition to this, you press or squeeze the part, and use any violence that is not necessary, you of course augment the inflammation still more. For this reason, in general, it is sufficient merely to make the puncture, or incision, and let the matter exude from it by itself. It is by no means necessary to squeeze the part; you are not to consider it a point of importance to empty the cavity of the abscess; for you observe that nature does not do that. She makes a small opening, and a little matter exudes from it; then it is extended by ulceration, and an additional quantity of matter is thrown out by it. The plan she adopts is not to get rid of all the contents; nor is there any advantage arising from it. If it is accomplished by pressing the circumference, there is not only no benefit, but a considerable disadvantage. Having made a puncture, or incision, cover the part with a fomentation for half an hour, so that the matter may be more considerably discharged by the gradual oozing from the sides of the abscess; then apply a soft poul-

tice, which you may continue till the healing process is accomplished.

Now it is of considerable consequence to determine what are the cases in which abscesses may be left to their natural course, and what are the cases in which it is desirable to make an artificial opening for the discharge of the matter. When the collection is near the surface, and when it is seated in an unimportant part, you may leave nature to herself, to do her beat. But there are various cases in which you wish to abridge the period of the inflammation, or to limit its extent; and for this purpose it becomes necessary that you should resort to the measure of artificially opening the collection.

I have stated to you generally, that the matter contained in an abscess gradually approaches to the surface of the body; but when it is deep-seated, and when, in its progress to the surface, it meets with textures of an unyielding kind, it cannot proceed; being resisted in its progress to the skin, it extends in other parts, where less resistance is offered. Thus, when matter is formed under the fascia of the thigh, for instance, which is a very tough and unyielding part, it will be a long time before it makes its way through; but it extends in all directions under the fascia. The abscess becomes larger in size than it would be if these particular circumstances did not exist. When matter is formed deep in a limb, among the muscles, it meets with more or less resistance, either from the fascia or tendons. Under all such circumstances, it is advisable to make an opening as soon as you have assured yourself that matter exists. You would, therefore, open an abscess early if it took place in the fore-arm, or the leg, or the thigh; and more particularly if the formation of matter took place in the palm of the hand, or the sole of the foot. There is such a density of fascia, and an integument so firm and unyielding, that the matter does not come to the surface when it forms in those parts; on the contrary, being confined, it makes its way between the tendons, and produces extensive mischief. You must therefore, as early as possible, open a collection of matter which takes place in those situations; and you must frequently make an incision, when you cannot, by the sense of fluctuation, or by external examination, ascertain that any matter has actually formed. The same observation applies still more forcibly to matter forming about the periosteum; for there the matter is confined by a firm texture, and if it is not let out, it extends to the whole line of the bone. When active inflammation takes place in a part where there is a large quantity of cellular tissue, there the abscess will become considerable, unless you discharge it early. This is the case about the anus and

the perineum; and more particularly in matter forming where there is a good deal of cellular membrane that is covered externally by muscles, as in the axilla, the groin, and the neck. In the neck, there is a considerable quantity of cellular membrane by the sides of the trachea, œsophagus, and about the carotid artery and jugular vein. These are covered by fascia; and it not unfrequently happens that the formation of matter takes place in the cellular membrane deep in the neck, and in consequence of the collection being covered by a firm texture, it has no disposition to make its way externally;—in fact, the matter will descend along the vessels of the neck, towards the cavity of the chest. There is not only this danger, but the patient suffers excessively during the time the matter is forming, in consequence of the large nerves and the important parts that are situated in the neck. Matter frequently burrows under the œsophagus and trachea; and you find active febrile disturbance under those circumstances. I have seen a patient, from matter of this kind forming under the jugular, delirious for several successive nights. Here you must proceed to make an opening as soon as you have obtained sufficient proof that matter has formed.

You will see, under the circumstances I have mentioned, that you are obliged to make an opening for the discharge of the matter, when it is seated so deeply that you cannot have the evidence of fluctuation as to its existence. What, then, is the evidence that convinces you that matter has formed? You must consider the symptoms that have attended the original progress of the complaint; you must consider the pain, and examine the swelling of the part. There is generally, in the formation of an abscess, a swelling of the parts, with serous infiltration, and it is a sign of considerable importance in determining this question. In cases of this kind, when the symptoms are very prominent, and, from the collection of circumstances that I have just mentioned, you have come to the conclusion that matter is probably formed, although you cannot feel a soft place, you are fully justified in making an opening, notwithstanding it sometimes happens that you do not discharge the matter. There is no harm in making a puncture even where there is no discharge. The matter is very deep in the cases I have mentioned, and you may have to penetrate the whole length of the blade; but if the abscess is seated in the neck, you must be chary in the part you select for making the puncture, so as to avoid the blood-vessels.

It is necessary, in cases where the matter lies deep, to make a free opening, because you cut through parts that are in a healthy state, and the sides of the opening will

speedily close by adhesion, and thus the further escape of the matter is prevented. You should therefore make a more free opening, under such circumstances, than if the matter approached nearer the skin. You must not only make such an opening as to prevent the parts from uniting by adhesion after a short time, but you must also put something between the edges; for we find that otherwise they adhere in 24 or 48 hours after the matter has been evacuated. You should also open the abscess as early as possible when it forms in any part of a dense unyielding structure—such as the finger, where, besides the tendons, there is a considerable proportion of blood vessels and nerves (and the process of suppuration occurring in a part highly organized, is always attended with excessive pain.) This rule applies to all formations of matter about the hand and fingers, the pain accompanying such being of the most severe kind, and you cannot too speedily relieve the patient from his suffering. Moreover, as all depositions of matter remote from the surface, in the palm of the hand, are apt to spread, and give rise to subsequent important mischief in the part, you must make an opening even though you are not certain that matter is formed. There can be no risk in the wound inflicted by a puncture; the worst that happens is, that you may make a puncture through the skin without actually discharging the matter.

When matter is seated near any of the great cavities of the body, or any of the large joints, it is proper to open the collection early; not that there may be great fear of the matter penetrating into those cavities, but because there is a risk of such occurrence. The matter itself produces no material effect on the parts; it does not corrode, or act chemically on any textures that come in contact with it. I was almost surprised at finding, in a work published at the present day, expressions which seemed to denote some remains of an opinion of that kind. I have read, within a day or two, of the approach of matter to the skin under the term of *erosion*, in an article which, in other respects, was extremely well written.

Another case in which a collection of matter should be opened early, is where it is produced by the introduction into the cellular membrane of an irritating fluid—such as an effusion of urine, or of fecal matter; more particularly if such effusion still continue. The only way to avert the mischief which will be produced by such an irritating cause, is to make a free and early opening.

When matter forms in certain parts which are of great importance to life, in consequence of their functions—such as in suppuration about the fauces or the entrance of the larynx; and, in fact, in any formation of matter about the trachea or œsophagus—it ought to be opened as speedily as possible.

With these particulars I shall conclude our enumeration of the cases in which it is important to open an abscess early, so as to anticipate the process of nature and produce an external discharge sooner than it could be accomplished by natural means.

In many of the cases to which I have alluded, it will be proper to employ such antiphlogistic means as are calculated to diminish the inflammation, which may be supposed to exist to a considerable degree. In any deep-seated formation of matter which you open in this way, you may, perhaps, apply leeches pretty freely to the part, or sometimes let blood. Thus, if you have a formation of pus, it may be necessary, in consequence of the surrounding inflammation, to take blood from the arm, or apply leeches, and frequently you may combine the two—open the abscess, to lessen the degree of mischief, and employ antiphlogistic means, to prevent the recurrence of inflammation.

CLINICAL LECTURE ON DISEASES OF THE SPINE.

BY CHARLES BELL, Esq.

Surgeon of the Middlesex Hospital, and Professor
of Surgery in the University of London.

[Continued from p. 298.]

You see by these specimens how the bones that have been diseased become united—that granulations of bone shoot from the upper and lower vertebræ, and running together, form an union between three, four, or more of them. The unyielding nature of this bony union throws the flexion of the spine on the parts above and below the exostosis, and one cannot but apprehend that the united vertebræ may be fractured. I had a case in the hospital very much like fracture, produced from this cause. You will observe that the spines of old men, like those of old over-laboured horses, are sometimes joined in this manner by ossification. A poor man in this condition had a weight fall upon his shoulders, which broke the spine, making a fracture across the new splint of bone.

Let me read this short note of a case, and I am sure it will frighten you with the possibility of fracture occurring.

A little boy attends the hospital as an

out-patient, who has a curvature of the spine forwards; the angle is at the fifth dorsal vertebra, and is very acute. It has existed for eighteen months, and has been gradually getting worse; yet he runs about—he has had no paralysis of the limbs—indeed he boasts of being an excellent player at leap-frog, or, at least, he is sought after by his companions to leap over, from his accommodating position.

This poor neglected boy, in his play, tumbles heels over head. Now, although there is in general some strange instinct which limits the exertions of a patient whose bones or joints are insecure, and spontaneous exertion is therefore generally safe, yet one cannot but apprehend danger to the spine, bent down to an angle as this boy's is, from such rude exercise.

Even the practice of an hospital, with private study, will not enable a lecturer to give a fair statement of the opinions of the day. I find in private practice, with some surprise, that issues are laid aside in this complaint. Now although perfect rest, and such remedies as will remove a scrofulous diathesis, are the means to be especially trusted to, yet a well managed issue is a good thing. Its use was established by the practice of Mr. Pott: the *rationale* is right, and I confess to you that we seem running sometimes in a circle, making no progress, from having too little regard to the opinions and practice of the last age.

John Dale, æt. 27, was admitted on June 16th, with a large swelling, situated above the anterior spinous process of the ilium, on the right side; and a projection of the vertebræ at the lower part of the spine.

He gives the following history of his complaint:—When he was 13 years old, he fell from a horse and injured his back; nine months after this fall he began to have a weakness in his loins; he could not hold himself erect, but had to walk with his hands resting on his knees. He was for seven months under Mr. Cline at this time, and it was observed that his spine projected at the lower part. In four months more he was able to walk about with ease, and he continued well for eight years. At the end of that time he began to experience the same pain in his back and distress in walking; he accordingly applied at this hospital for relief, where he remained for some time, and had issues placed in his back. Having left this hospital, he remained free of any complaint till five weeks before his readmission, in June last; he then was alarmed by finding a large tumor, twice the size of the fist, forming just above the spine of the os ilii. This was lanced five different times, and evacuated a great

deal of matter; the orifice was healed each time after these operations, but at length the abscess burst of itself, and it has continued discharging matter, frequently to the amount of a pint a day, ever since that time. He has suffered from hectic fever twice during the time he has been in the hospital, and was very dangerously ill; but at present the discharge from the abscess is becoming somewhat less, and his strength is improving greatly.

The spinous processes of seven vertebræ at the lowest part of his back are prominent; the second or third lumbar appears to be the one which is most prominent, or that which forms the angle.

In this case you have that combination, for which you will always be prepared, of lumbar abscess with carious vertebræ. I shall not detain you with any observations on lumbar abscess; but shall say a few words on the cause of the paralysis in diseases of the spine. Two facts are here essential: first, that the paralysis of the lower extremities precedes the sinking of the vertebræ; and, secondly, that the muscular power of the limbs is recovered, although the distortion remains very acute. The paralysis is not, as you would imagine it, the effect of pressure of the bones, but a consequence of the inflammation of the spine affecting the spinal marrow. This, at least, is consistent with the instances which you have had to-night, where the patients preserved the same posture, whilst the weakness of the lower extremities and the power of propelling the urine varied with the circumstances of the case. This also tends to explain that very curious circumstance of a patient having the power of moving the limbs remarkably diminished, whilst he retains, in an almost natural degree, the sensibility of the integuments; for, undoubtedly, the destructive process that is going on in the bodies of the vertebræ, may be presumed to injure the anterior column of the spinal marrow more than the posterior. However that may be, I must state what you will find in practice. A child, which was formerly running about, is again obliged to be put on the mother's knee; and she tells you that the legs and thighs which were firm, enabling the child to stand upon her knee with little support, are now loose, soft, and flabby: the muscles have a woolly texture, as it were. Perhaps the patient may be farther advanced; he may be a boy at school, for instance, and the feebleness in his leg

is first shown by his frequently tripping and stumbling. The commencing paralysis of the legs is not exhibited in actual want of strength, but in the defect of the adjustment of the different classes of muscles, and consequently the want of power of accurately directing the toes to the ground. When these symptoms draw attention, and the spine is examined, there may be no remarkable curve in the back, yet there will be a tenderness in the bones, and a puffiness of the integuments over the diseased vertebræ. You will attend particularly to this state of the integuments. It arises from the same cause, and is of the same nature with that colourless tumefaction in the skin which prevails in scrofulous inflammation of the joints. The state of the integuments over the diseased vertebræ indicates the condition within: when the disease is progressive, the tumefaction obscures the knobs of the bones; when, on the contrary, you feel every process of the vertebræ distinctly, it is a fair harbinger of the favorable termination of the complaint.

But since I have spoken of the disease in childhood, be careful not to be thrown off your guard here, and mistake for the effects of scrofulous disease of the spine that *partial* paralysis which affects children. This is a very obscure part of pathology. It is not the subject of to-night's lecture; yet let me state, though shortly, emphatically, that it is a very frequent source of mistake in practice. In adults, also, you have paraplegia; where it is very natural to suppose the spine is the cause, from the muscular power being cut off at an accurately defined line. In examining the trunk, when you press at that part which is just at the limit of the sensible and insensible parts, the patient is apt to say he has pain in the vertebræ. Be on your guard against deception here, and remember, that the lower parts of the body may be alone affected, while the disease is in the brain. When you suspect this, you not only inquire for such symptoms as pain in the head and affection of the eyes, but attend very particularly to the motions of the arms. The patient may move about his arms and shoulders, and say he has perfect power in them; and yet there may be a defect of motion visible, as in his manner of writing, or in a want of due correspondence between the motions of the finger and thumb.

This subject is very extensive, but there is one circumstance more that I shall touch upon. You must have observed in one of the cases that the child suffered pain in the side when the shoulder was pressed down, and in truth it is not an unfrequent occurrence to find a patient with curvature of the spine distressed with pain in the lateral and anterior part of the chest. You will be careful to observe whether this symptom does not arise from the pressure of the vertebræ against the ganglions of the nerves. There is a preparation before me which shows how much the foramina for the exit of the nerves from the spinal tube are diminished on the contracted side. Both in the lateral curvature and the scrofulous disease of the bodies of the vertebræ, this is a symptom worthy of your attention; lest believing these pains to have an inflammatory origin, you may be prompted to use means to remove them which shall only the more distress the patient, and reduce his strength.

We have been drawn so far into a complete lecture on the injuries of the spine by the necessity of attending to those occurrences in the hospital which you have witnessed, that I shall not touch upon the subject again in the present session, but proceed to explain some specimens in my hands, and to notice some cases, although they have not occurred in your time. It is probable that your professor of anatomy has explained to you that the structure of the bones of the spine is very light and delicate, and that the vertebræ would not, in fact, be capable of sustaining the pressure they are subjected to, were they not held together by universal coverings of ligaments, and by the elastic intervening cartilages, which, by their resiliency, break the force of the shocks that would otherwise fracture the column. It is apparent too on the consideration of the anatomy, that the vertebræ of the neck have a freer motion on each other than in the other parts of the spine; that their motions are less checked by the forms of their processes; that the strength of the column here results more from the ligamentous bindings, and that these are therefore more complicated. This remark applies particularly to the motions of the head upon the atlas, and of the atlas upon the vertebra dentata.

It has been a question whether there can be such an accident as a true luxa-

tion or dislocation of the vertebræ. We have in the first case seen that the vertebræ of the neck may be dislocated to the extent of bruising the spinal marrow, and destroying its function; and I have had an instance of dislocation of the lowest dorsal from the highest lumbar vertebra, in which the spinal marrow was completely torn across. In that case, the strength of the ligaments tore up the shell of bone to which they were attached, so that some might affirm it was a combination of fracture and dislocation. We must distinguish, however, such a case from the fracture of the bodies of the vertebræ, which is a very common occurrence, in consequence of violence crushing down the spine. But I wish you to attend to the accidents occurring at the highest point of the column. I shall not even enumerate the ligaments that hold these bones together and check their motions (which, however, form a very beautiful mechanism, well deserving your attention); I shall merely remind you that, as ligaments are peculiarly subject to scrofulous disease, so are these; and that, when they become inflamed, they soften and relax so as to give way and permit dislocation. It is this which makes it dangerous to play with children in a manner to bear rudely on these ligaments. I dare say you know the way in which thoughtless young men will take a child up by the occiput and chin, and swing him: so common is this practice, that there are some words used while doing it, in different countries; such as, "Now, my boy, I shall shew you London;" or "I shall shew you your grandfather;" which latter I deem the more appropriate phrase, as such rude play may suddenly introduce the child to his ancestor! You will find this case related by the celebrated Petit. A child is stated to have run from one shop into another, in Paris; where the good-natured, foolish shopman, took him up in this playful manner, and after swinging him a little, saying "qu'il allait lui faire voir son grand-père," set him down upon his feet, —when, behold, the child was dead. It happened, singularly enough, that the father of the child, a saddler, coming suddenly in upon the scene, was so enraged that he threw the hammer used in his trade at the unfortunate shopman, and struck him on the back of the neck, between the first and second vertebræ, producing instant death: a singular kind of retribution,—more

illustrative of the surgical point than according with our sense of justice. You are aware of the circumstance which gives tenfold importance to this part of the spine—that the spinal marrow here does not merely command the voluntary motions and sensibilities of the body, but the respiration and expression also: so that death from an injury of this part occurs with frightful suddenness—there being neither struggle nor cry of anguish, nor expression of any kind. But it is not from scrofulous weakness alone that there is danger: I have seen two instances of sudden death, from dislocation of these vertebræ, in consequence of venereal disease extending from the throat.

Whilst such occurrences as these must not be forgotten, I have to shew you some specimens which evince facts that appear at least in singular contrast with them. A man was brought into the Middlesex Hospital, in a state of insensibility, those who brought him stating that he had fallen from a height. The appearance of the head did not indicate any violence inflicted there, but towards the next morning he expired. I hold this singular specimen in my hand. The margins of the foramen magnum of the occipital bone were driven up into the cavity of the skull, and here they are. The portion of the occipital bone, you perceive, is attached to the atlas by ossification; and the atlas is, in the same manner, ankylosed to the vertebra dentata. The specimen, then, exhibits ankylosis of the head to the vertebræ, and of the vertebræ to each other. You see, too, that the vertebræ lie obliquely, and that the ring for the transmission of the spinal marrow is encroached upon in a remarkable manner*. After the discourses you have had, these appearances are to you the indications of

* We subjoin a more minute account of the preparation after examining it in the museum. The atlas is united to the occipital bone, without there being any displacement of these bones: the dislocation has been altogether between the atlas and the dentata, which are firmly united together. The left articulating process of the atlas has been pushed forwards to the extent of very nearly an inch beyond the corresponding articulating surface of the dentata, and has become united to the fore-part of the body of the dentata. The articulating processes on the right side preserve their natural relations pretty nearly: the atlas on this side being only a little advanced before the dentata. The consequence of this shifting of the left articulating process of the atlas is, that the ring formed by the occipital hole and the atlas together does not correspond with that of the dentata: the posterior margins of the foramen magnum and of the circle of the atlas lie across the very centre of the

injury and violent inflammation at a former period; and they are proofs how much this very part of the spine may be deranged, and the spinal marrow retain, or at least resume, its function.

We may incidentally observe, that the loss of elasticity by this defect of the natural structure of the vertebræ, probably gave force to the shock against the head, which caused the fracture of the cranium. We may observe, too, that the injury may have been produced either by the man falling upon his head or on his feet, or breech. If the servant-maid wishes, for example, to fix the broom upon the broom-stick, she is but an awkward wench if she attempt to thrust the head of the brush upon the shaft with her hands—but she takes the shaft in her hand, and striking the end smartly upon the pavement, she more effectually fixes it; for the head of the brush being interrupted in its rapid descent, the shaft is wedged into it. So will a person, falling upon his feet, have the spine, you see, wedged into the skull: and here you have a proof, amongst many which I offered you in the physiological lectures, of the happy adaptation of the natural and perfect spine to support the head without a jar, from observing the consequence of the defect of its structure.

But I take another specimen in my hand—a better proof still of the violence the parts may sustain here without death ensuing; and which, indeed, when I present it to you, must appear something like the puzzle of steel rings upon a rod. How is it possible that these two vertebræ, the atlas and den-

tata, should thus stand one before the other, soldered together by new bone, presenting two horizontal rings? How came these rings to stand thus, on the same plane, without the spinal marrow being torn asunder?—for not only was the spinal marrow not torn asunder, but the man survived the accident for six or eight months. I must observe, that this specimen has been presented to me by our medalist, Mr. Phillips; who, in procuring it, evinced that early ardour of investigation which has been so happily followed by severe application to study in this place.

The patient was 34 years of age, a farmer's servant, and a strong muscular man. Being employed in forming a hay-rick, he fell headlong from the top, the height of sixteen feet. He was at first stunned by the fall, afterwards he complained of severe headaches. He had no paralysis, and was soon able to leave his bed. The surgeon who first attended him bled him twice, and gave him purgative medicines. In the course of a month, as he was not getting better, he left his village, and became the patient of another surgeon. There was at that time an appearance of enlargement about the second and third cervical vertebræ; the patient could not bear to move his head; he complained of severe pain at the back part of his head, and there was some diminution of the sensibility in the upper extremities. Leeches were repeatedly applied to the back of the neck and the occiput, and he was laid on a firm mattress without a pillow, his head being kept at rest. In the course of a month or six weeks, there being little amendment, the surgeon directed an issue to be placed on the situation of the enlargement of the vertebræ, and another on the occiput, and he took the liquor potassæ. At the end of another month the sensibility of the chest, and of the upper extremities, seemed more impaired, and his deglutition was impeded. These symptoms continued during three months, with alternate aggravation and remission: at the end of which time the difficulty of swallowing was increased to an alarming degree, and his breathing was also affected. He had an attack of pleurisy, for which he was bled two or three times. About a fortnight after recovering from this attack, symptoms of general dropsy came on. Erysipelas appeared near the situation of the issues; the powers of life were reduced extremely low, and he died with the symptoms of hydro-thorax. Much difficulty was

tube or ring of the vertebra dentata, thus closing up exactly one half of the canal. A process of bone,

about three-quarters of an inch long, extends forwards from the fore-part of the processus dentatus to the surface of the atlas, on which it had formerly been articulated. A common-sized pencil can only be passed from the occipital foramen down into the canal of the vertebræ.

experienced in procuring the portion of the spine for examination. There was no appearance of injury to the medulla spinalis; the passage of the pharynx was almost closed by the projection of the atlas into its cavity.

The only explanation of this preparation seems to be that the posterior part of the atlas being broken off, and remaining attached to the edge of the occipital hole, the lateral and anterior part of the hoop of this bone was forced forwards, and then the occiput sank down upon the second vertebra. The separation of the first vertebra into two parts allowed the occiput to sink down on the vertebra dentata, and the two ends of the anterior portion of the atlas coming in contact with the fore-parts, the body of the vertebra dentata united with it by ankylosis, so that the body of this second vertebra has one ring, its own proper one, projecting behind, and another attached to its fore part. The spinal marrow did not suffer by this shortening of the tube, as we have seen it did in the oblique shifting of one bone upon another.

I shew you another specimen, where the upper vertebræ are run together by ankylosis, but unaccompanied with any twist in the spine. What is remarkable, and yet might have been expected here, is, that between the third and fourth vertebræ the articulation has been more free than is natural; the processes have been absorbed, and have adapted themselves so as to admit of a greater extent of motion between them, proportioned to what was lost by the ankylosis above. This I can only tell you was taken from a very old man, who died from strangulated hernia. I am inclined to believe it to be of that class of diseases of the spine which I have already noticed as peculiar to old age; and it may have some resemblance to the poll-evil in horses, though not arising exactly from the same cause; for in them I believe the injury at the occipital joint is caused from the powerful operation of the reins on the long head, which is as a lever, while suddenly checking the animal.

On the whole then you see, that an accident to the upper vertebræ of the neck may bruise the spinal marrow, and cause death as suddenly as when an animal is pithed, and that when disease takes place slowly in these vertebræ, the spinal marrow is protected from the communication of the disease

by the sheath, that sheath being strengthened in a remarkable manner by the fibrous and ligamentous substance which comes down from the margin of the foramen magnum and the basilar process of the occipital bone, and goes like a funnel into the tube of the vertebræ. When these ligaments, however, are weakened by disease, dislocation and subluxation may take place. Those of you who come from sporting counties may, perhaps, think yourselves familiar with the case of dislocated neck. The jockey when reining in, after passing the winning post, brings the horse into a motion like the leaping of a deer, and it is then scarcely possible to keep the saddle; the boy is thrown, and lights upon his head, and is taken up with his head hanging upon his shoulder. They set about reducing the dislocation, by putting their knees upon his shoulders, and drawing upon his occiput and chin. But should he happen to recover during this operation, or soon after it, it has still nothing to do with dislocation: it is a case of concussion, and the recovery does not result from the operation. Luxation of the head is fatal.

But subluxation may take place without death. This is a consequence of twisting the head round, as in looking behind you, and the articulating process of the atlas escapes from the corresponding surface of the dentata. It is difficult to resist the temptation to reduce such a displacement, but we have very high authority against the attempt of reduction. A surgeon of the Hôtel Dieu, against the authority of Desault, on a child being brought to him with its neck twisted, took it from its mother's arms, and set about reducing the subluxation,—when the child suddenly expired. If a child have disease of these higher vertebræ and their ligaments, the unhappy mother is much to be pitied. The child is fretful, and crying continually. When laid in bed, the inflamed articulations are twisted by the position of the head: however carefully he may be lifted, there is still a motion in the neck, and his screams are redoubled. I have found nothing better than forming a collar, which shall fill up all the inequalities between the shoulders and the ears, and between the breast and the chin, so that the child shall be swaddled like the infant of an Indian woman. This alone gives a check to

the motions of the head upon the neck, and, with a seton drawn under the occiput, affords some hope of cure; when you may once more see the extent to which the diseases of these parts may go, and life be saved.

I am now more free to recommend you books, as you can, after lecture, retire into the library with every comfort and convenience. For these subjects consult Mr. Pott's works; Sir J. Earle's; Mr. Brodie's; a paper in the *Transactions of the College of Physicians*, by Dr. Baillie, on Paraplegia; and the works of Dr. Abercrombie. With regard to the accidents at the upper part of the spine, consult Boyer, and an excellent and circumstantial paper by Mr. Lawrence, in the *Medico-Chirurgical Transactions*. For the first subject which we have treated of, you will find Mr. Shaw's works the best to consult.

SUCCESSFUL LIGATURE OF THE CAROTID ARTERY,

For Sloughing in the Throat, with Hemorrhage.

To the Editor of the London Medical Gazette.

SIR,

THE following case occurred to me a short time since in practice: it appears to me of sufficient interest to lay before the professional public. Will you, therefore, oblige me by giving it insertion in your *Journal* at your earliest convenience.

I am, Sir, yours, &c.

J. LUKE.

1, Broad-Street Buildings,
Nov. 20th, 1829.

T. B. ætatis 45, a tall, rather muscular man, of sanguineous temperament, captain of a coasting vessel, trading between Cornwall and London, while in the former place, was stung by a wasp on the wrist, which became much inflamed, attended by a pustular eruption around the part. Livid red blotches, about three days after the sting, appeared on the trunk and extremities, with fever, neither of which created any alarm. With these upon him he went on board his vessel, bound to London. On his passage he had the misfortune to take cold, and was affected with sore

throat, requiring confinement to his cabin. In a week he arrived in London, much worse, at which time he was visited by Mr. Gayton. The soreness, however, increased, and the difficulty of swallowing was very considerable. He experienced much pain, particularly in the left side, where he was convinced a "gathering" had formed. His opinion was confirmed on Sunday, Sept. 27th, by the bursting of an abscess, with partial relief. Together with the matter he passed about six ounces of blood by the mouth. He was still sensible of another gathering lower in the throat than the first, on the same side; and exhausted as he was by disease, he began to entertain apprehensions for his safety. On Sept. 29th he was brought on shore, and took up his residence with a friend in the neighbourhood of my house. On the eve of this day, the second abscess burst, and shreds of slough came away with the matter: by this he was much relieved, and slept the greater part of the night.

Sept. 30th, three weeks from the commencement of his illness, I was called to him about 4 o'clock in the morning, in consequence of his having lost a large quantity of blood. He had been awake by something flowing from his throat, which proved to be blood. When I arrived he had already lost about half a wash-hand basin full of blood; and shortly after he vomited more than two pints of coagula, making altogether between four and five pints lost in about half an hour. I found him in the greatest state of exhaustion; his pulse was scarcely perceptible, and very rapid. There was extreme paleness of the lips; the eye sunk in the orbit; a clammy sweat upon the skin; inclination to vomit; and he could not speak louder than in whispers. On attempting to examine the throat, I could see nothing behind the soft palate, to which were adhering shreds of coagula. In a short time he began to revive, and his pulse became more perceptible. Ordered one grain of the acetate of lead, with a quarter of a grain of opium, every two hours; goulard lotion, with equal proportion of spirit, to be applied to the throat; the head to be elevated on a pillow, to be kept perfectly quiet, and abstain from swallowing as much as possible.

12 o'clock.—The faintness has gone off, and he is much revived. He com-

plaints of thirst, and of pain of his left shoulder and elbow, which, however, may be pressed without inconvenience. The wrist is still inflamed. Ordered to continue as before directed, and to use a lemon to quench his thirst.

Oct. 1st.—Has slept soundly after taking fifteen drops of liq. opii sedativus, and is improving in appearance. The blotches are still visible in various parts of the body, resembling the remains of bruises, which he states they were like when they first appeared. They are not painful, nor raised above the surface. The disease has been clearly the *purpura hæmorrhagica* of Bateman. Ordered to continue as before, and to take a small quantity of beef-tea.

Oct. 3d.—About 4 P.M. I was again called; bleeding had returned, but had ceased before my arrival. In about a quarter of an hour he had lost between three and four pints of blood: his pulse, however, was not much reduced in strength, nor increased in frequency, nor did he appear much exhausted. He spoke in whispers, and complained of the throat, and pointed to the left side of the os hyoides as the seat of pain. From this part, during the bleeding, he felt a jet issue into the throat: Ordered to continue the acetate of lead and opium, and in addition half a grain of powder of digitalis every two hours.

Oct. 4th.—At 4 A.M. bleeding again returned. From the account I received I expected to find my patient dying or dead. I found him in the greatest possible state of exhaustion; faint to nausea; the pulse with difficulty to be felt, and very rapid; the breathing laborious, and extreme paleness of the countenance. He was sensible, but apparently indifferent to surrounding objects. He had lost at this bleeding more than three pints of blood. It seemed almost certain that he must die. After a short time, however, he began to revive; the pulse became more distinct, and breathing more free, but the powers of life were so far reduced that another bleeding would inevitably prove fatal. I therefore determined to tie the carotid artery on the left side, that being the trunk which the circumstances of the case indicated to be the source of the bleeding vessel. To obtain the advantage of day-light, the captain was seated on a chair near a win-

dow. Before, however, he was arranged for the operation, his face became convulsed, the pupils of his eyes dilated; his head fell upon his shoulders; and his pulse and respiration ceased. In this state he was hurried back to bed, with the impression upon my mind that he was past hope. A few minutes shewed that he had only fainted, and he soon revived. His head was then laid over a pillow at the foot of the bed, and as the room was dark, I was obliged to proceed by candle-light. An incision, of about three inches through the skin, exposed the platysma hyoides, which was divided along the inner border of the sterno-mastoideus muscle. This being drawn to one side exposed the omo hyoideus crossing the sheath of the vessels, which was then cut through. The carotid could be very indistinctly felt pulsating in its sheath, into which last I made a small opening; a director was then introduced to detach the artery from the accompanying nerve and vein. This being done, a needle, armed with a double ligature, was carried around it from the outside, without bringing into view either the nerve or the vein. The ligatures were separated, and tied about half an inch apart, and the wound closed with plaister. On being questioned, he said he did not experience any unusual sensation when the ligature was drawn tight. His pulse was very weak, and beating 120 in a minute. The pupil of the left eye more dilated than the right. He was kept in the same position as during the operation, except that his head was not so much extended. Ordered beef-tea and light drinks.

11 A.M.—Is a little revived, and has been tranquil since the morning. Pulse 110, and weak; breathing natural; skin warm; the tongue dry; and there is thirst, but he is free from pain. Ordered to continue the beef-tea, and use lemon to quench his thirst.

8 P.M.—Has slept since the last visit, and is going on well.

Oct. 5th.—Has slept well through the night without medicine; pulse 100, and stronger; the colour has partially returned to his lips; his spirits are better, and confidence of recovery increased. He complains of a slight numbness extending over the forehead. The bowels have not been relieved.

Oct. 6th.—The numbness has left the forehead, the pain of the throat

has subsided; and he swallows without much difficulty. He is improved in strength.

Oct. 7th.—The wound was dressed, and found to adhere for half its extent. He has been feverish and restless during the night, and his sleep disturbed by dreams. In the evening, he spat up about an ounce and a half of saliva, tinged with blood, by which he was considerably alarmed. His bowels have not been opened since the operation.

Ordered a draught of infusion of Senna and Sulphate of Magnesia immediately. ℞j. Infusion of Roses, and gtt. xv. of Træ. Digitalis every six hours; and Syrup of Poppies to appease the uneasiness of his throat.

Oct. 8th.—Has passed a restless night, but is now better. The bowels have been opened five times. The feverishness and uneasiness of his throat have subsided. For the first time, I could make an examination. There was a slight fullness only to be seen on the left side. His appetite is good and spirits revived; and he swallows with ease.

Oct. 11th.—There has been again fever and irritation of the throat; he has also spat up about two ounces of blood, and is much alarmed. Bowels confined. Ordered to repeat the opening draught, as occasion may require.

Oct. 16th.—He left off the digitalis on the 13th, in consequence of a headache, which was attributed to its use. He has been daily improving, and the wound looks healthy. There is no pulsation to be felt in the carotid above the ligature, nor in the temporal artery. The opposite carotid beats with unusual force. The pupil of the left eye is more dilated than the right, but he can see equally well with both.

Oct. 20th.—He requires to take opening medicine frequently, otherwise his bowels become confined, and fever supervenes. There is a good deal of irritation of the gums, arising from collection of tartar around the teeth, and a gum-boil has formed since yesterday over the incisor teeth, filled with congealed blood. Ordered an opening draught, and to wash the mouth with muriatic acid gargle, in the proportion of x gtt. to the pint of water. The ligatures were twisted, to expedite their separation.

Oct. 26th.—The ligatures were taken

away, being the twenty-second day from their application. The gums are better, and he is going on well.

Nov. 7th.—Has been down stairs daily since the 26th, and now is enabled to call on his friends and to transact business. He has no unusual sensation, but is weak, and becomes fatigued soon. Pulsation has returned in the arteries above the os hyoides, but not in the trunk between this bone and the place where the ligatures were applied. The wound is not quite healed: he, however, proposed to leave town shortly for the country. He left town a few days after the last report.

SMALL POX.

To the Editor of the London Medical Gazette.

SIR,

CONCEIVING that a deal of unnecessary alarm exists throughout the country regarding the prevalency of small-pox, I would earnestly direct the attention of my medical brethren to the concise and admirable letter of Dr. Clarke, on variola after vaccination, which is inserted in the fourth volume of the Transactions of the Association of Fellows and Licentiates of the King and Queen's College of Physicians in Ireland.

Being attached to an institution whose admissions average 4000 annually, and situated in a populous manufacturing district, I seriously declare small-pox to be seldom seen by me. For the benefit of those who may not be able to obtain a perusal of the work I have referred to, I will transcribe the following passages of Dr. Clarke's letter:—

“Much of the alarm which has arisen on this subject, and which still continues to agitate the public mind, appears to me to have been produced by want of due attention to a few words of Dr. Cullen's definition of variola—‘*Papulæ phlegmanodæ, quæ spatio octo durum in suppurationem abeunt.*’ Can it be deemed unreasonable to ask practitioners to keep these words constantly in mind, and to wait with patience till the *eighth day* after the eruption has made its appearance? If pus can *then* be found in the pustules, the existence of variola can no longer be doubted; but until this period arrives, no prudent man should venture posi-

tively to decide. Let it be remembered that varicella is defined by the same high authority — ‘*Pustulæ, variolæ similes, vix in suppurationem euntes, et post paucos dies desinentes.*’

“In several recent instances variola and varicella have been confounded by practitioners of experience and ability. These errors must have arisen from opinions formed before the *duration* or *contents* of the pustules could be ascertained. The purport of these remarks is, to guard my brethren against hasty and erroneous judgments, which unnecessarily disturb the peace of families, and tend to throw discredit on a practice eminently calculated to preserve human life, and to lessen human suffering.

“During the last few years, I have seen many cases of spurious eruption, very like, in all the symptoms, to severe small-pox, for the first eight, nine, or ten days from sickening. On the sixth day of the eruption, or at latest on the seventh, the pustules declined rapidly, the fever subsided, and on the eighth day not a vestige of pus was discoverable. Had these been cases of genuine variola, the patients, instead of amendment on the sixth day of eruption, would have remained in a state of increasing danger for many days, and would have experienced a slow recovery.

“That every case of vaccination, however skilfully conducted, affords perfect security against small-pox, I do not pretend to affirm. Nothing human is perfect, and however apparently simple the practice of vaccination may appear, perhaps we have still much to learn.

“In proportion as it becomes more extended, and gets into the hands of ignorant men, we may expect failures to multiply. We know and lament that several such cases have occurred this year (1823); but we also know, that since the beginning of this century, when vaccination was introduced generally among the upper ranks in Dublin, no family has lost a child, in previous good health, by small-pox after vaccination; nor has even one eye been extinguished by this pestilential disease, so far as I am informed.”

RICHARD MOULSON.

Halifax, Yorkshire,
Dec. 1, 1829.

LIFE ASSURANCE COMPANIES.

To the Editor of the London Medical Gazette.

SIR,

IN your number dated the 14th inst. is a letter containing many reasons why a medical man should not receive a fee for his certificate, granted to persons desirous of being assured. Certainly a certificate may be sought by an intimate friend—by a patient whose family he may have attended for years—or the health of the party may be such as to require no more than the simple declaration that it is good or bad. In all such cases, I presume, that either friendship or good feeling would prompt the physician to decline a fee, if it were offered.

But it appears to me that there are applicants for certificates who are not entitled to this consideration. It often happens, for instance, that the person whose state of health the physician is called upon to certify, is not interested in the property to be assured; and that there is no connexion between the physician and the party proposing the assurance.

I have been desired to report upon the health of a person whom I have not seen for some months, or even years. Accordingly an interview has been necessary, and more time has been spent in recalling the character and circumstances of the disease in which I had attended him, than would have sufficed to prescribe for two or three patients.

I have also been required to report on the health of persons whom I have never attended, who may have resided, during many years, in my neighbourhood, without having had occasion to employ any medical man; and a personal investigation has been unavoidable.

There is yet another class of persons, from whom, I submit, a more than ordinary fee is due—persons whose lives are avowedly not select; the value of which may be very much over or underrated, without a minute, and oftentimes tedious investigation, into the nature, situation, and probable danger of any admitted disease.

In all such instances as the above, I

see no reason why the fee should be withheld; the demands upon medical men for their gratuitous services being already inordinately great.

Your correspondent asks—"Suppose the fee to be given, from whom is it to come?"—From the party seeking to be benefitted—the party proposing the assurance, who may be neither friend nor patient?

"Can a medical man put the fee into his pocket with one hand, and with the other sign an unfavourable report?" Certainly not, if it be at once evident that the life is not insurable; but if the case requires investigation, he ought to be paid for the professional occupation of his time, and his report of course is to be true.

I have the honour to be, Sir,

Your obedient servant,

JAMES PLAYFAIR.

Plymouth, 30th Nov. 1829.

PROTRACTED UTERO-GESTATION.

An interesting discussion on this subject took place at the Westminster Medical Society on Saturday the 5th inst. J. Bacot, Esq. in the chair.

The importance of the question warrants us in placing on record the opinions which were then expressed by several of our most eminent practitioners in midwifery; we therefore subjoin a very full report of the proceedings.

DR. GRANVILLE, by whom the subject was brought forward, rose and said—Sir, if I rightly apprehend the objects of this society they are these: to instruct the junior members by the narrative of important cases, and the exposition of useful points of practice, derived from the experience of those who have the advantage of seniority; and, secondly, to discuss general principles applicable to questions of peculiar interest to the world at large. The subject I have selected for our consideration this evening belongs to this latter class. Its discussion will necessarily be confined to those of the members who have had much experience in obstetrical physiology; but I do not, on that account, fear any lack of argument or facts when I consider how many there are

amongst us, possessing the requisite qualifications for carrying on an animated discussion; and, therefore, do I trust that the time employed for that purpose will not be vainly expended.

The question of protracted gestation may be viewed under three distinct aspects—

1.—What is meant by protracted gestation?

2.—Is protracted gestation possible?

3.—How can it be proved?

The first branch of our investigation involves the consideration of the natural period of gestation in women; its attendant symptoms, and the means of recognising pregnancy.

These considerations embrace a variety of subordinate points of discussion, which, in a medical society, must prove of no inconsiderable interest.

The second branch of the investigation is also fruitful in subjects of discussion. The legal part of the question, properly speaking, begins here; the testimony of men is here to be appealed to and sifted; and the opinion of people of different nations, ancient as well as modern, who by their legislative enactments on the subject of protracted gestation have shewn what they thought of such a phenomenon: such an opinion, I say, must be taken into account.

The third branch is the most thorny, yet, to society at large, the most important; for on the negative or affirmative answer, which the question, "can protracted gestation be proved?" depends the preservation or violation of some of the most sacred rights—some of the most cherished feelings—some of the most endearing affections. The succession to hereditary honours, the inheritance of wealth, have often hung doubtful on the settlement of this part of the question; as have the preservation of an unsullied name, or an unstained reputation, without which life itself is less than worthless.

What other question, therefore, can be more important to us than that which I have the honour of bringing this evening before the consideration of the society?

And now for the first branch of our investigation: "What is meant by protracted gestation?" Literally it means that gestation which, reckoning from the moment of conception to the moment of parturition, lasts longer than

the time admitted generally to be the more *usual duration*. But are we in possession of positive evidence which fixes the more *usual duration* of pregnancy in women? I, for one, say nay to that question. It is usual to believe that nine months are the *ultimum tempus pariendi*; but who has proved it by actual experiment? On the contrary, such is the vague notion entertained on this subject by those even who consider the period of gestation an invariably limited one, that some call it forty weeks, and others nine calendar months; as if the one expression were synonymous of the other, although there be a difference of ten days between them.

Doctor Clarke, in his examination before the Lords on a recent trial, said, that "undoubtedly labour must begin at the expiration of forty weeks after the last sexual intercourse;" but when asked to prove it, he was puzzled, as every one else would have been at a similar question. He, however, spoke of examples in his practice where he could assert positively that forty weeks had been the *ultimum tempus*, because the parties interested said to him that intercourse had taken place on such an occasion, and "once only, and for good." Taking for granted that these communicative physiological ladies or gentlemen were not deceived or deceiving, what was the number of such cases known to the doctor? why, about twenty, he said. Surely such a *sum total* cannot be considered a sufficient demonstrative evidence for adopting the proposition that, *undoubtedly* the labour *must* begin at the expiration of *forty weeks*.

I lay stress upon the difficulty of ascertaining the *usual* period of gestation, because it will account for the difficulty also in which the question of protracted gestation is involved.

What means are we really in possession of for ascertaining by calculation the time when a woman will be delivered: the cessation of the menses, or the first appearance of symptoms denoting the occurrence of pregnancy, or the phenomenon of quickening? The first is fallacious, for there have been women who have menstruated for some months after they had become pregnant; and of such cases I have seen myself a good number, in some of which I had an opportunity of procuring portions of the men-

strual fluid and comparing it with some other; and there are many women, also, who become pregnant without menstruating at all between one pregnancy and another. This is the case with several who suckle their children. Nay, I have known cases where young women who were amenorrhoeic for some months before marriage, did, nevertheless, conceive, and bring forth in due time after marriage without once menstruating first.

As to the fallacy of the signs of pregnancy, I believe it to be proverbial and undisputed. Nothing short of the movements of the child can be adopted as a criterion; but when the movements of the child are felt, what date are we to assign to the pregnancy, so as to calculate its *usual duration*? The notion that a woman quickens when half gone, is absurd as a general proposition. There is, perhaps, more variety in this respect than in any other symptom of pregnancy. This third source of calculation, then, fails us; and we are, in fact, left to guess. Hence, when we are consulted on this subject by patients, what do we say? Why we ask the question when the patient had been last regular; and splitting the difference between that period and the next which the patient has missed, we calculate from that time, and reckon forty weeks. But how many such calculations of the days of parturition prove incorrect, even to a week, a fortnight, or a month? Ah! a great many.

I shall tell you presently how I come in possession of such and other illustrative cases; for the present I will assert, that, out of one hundred such reckonings, thirty at least prove incorrect—whether the calculation be made by the female herself or by her attendant accoucheur.

Still we may safely adopt the general notion—that 280 days is the more *usual duration* of pregnancy. Well, then, the meaning of protracted gestation is a pregnancy which notoriously extends a certain number of days beyond 280.

This leads us to the consideration of the second branch of our inquiry—namely,

Is protracted gestation possible?—My answer is, *certainly possible*; because there is nothing in such a notion contrary to the laws of nature. A child

sojourns in its mother's womb forty weeks: why could it not sojourn forty-one or forty-four as well? Are we so well acquainted with the marvellous action that comes on to expel the child at a particular period, that we shall venture to deny the possibility of such an action being arrested, by any cause whatever, for a longer period than *forty weeks*? What is there in the physiological considerations of this problem, which those who deny the possibility of protracted gestation can invoke in their favour, to silence us at once who support the contrary doctrine? They say, forty weeks are required to bring the child to maturity, and no more; but will they deny that many weeks less than that time have been known to be sufficient to bring the child to maturity? In other words, will they deny the possibility of *anticipated* birth, the child being in all respects full grown? Has nature not hundreds of such exceptions; and if so, why should the period of human gestation be so circumscribed? Dr. Rodman, of Paisley, states, that, in 1815, he delivered a lady, the mother of five children, who was confident, on one occasion, that the period of gestation had not extended beyond nineteen weeks. The child lived. Professor Broussais, in his *Essay on Medical Education*, relates the case of a woman who brought forth a live child, which lived to maturity, six months after a previous labour. Broussais was witness to the labour. Now here the child was fit to live at five months and a half. Such cases of exception would have been reckoned fabulous had they not occurred in our own time, and vouched by medical men of high character, being personal witnesses of the facts they narrate. Nature, in fact, is made up of exceptions. Again: if we deny the possibility of protracted gestation, we must of necessity adopt a more extraordinary phenomenon as true—namely, that of *superfoetation*—to explain certain cases (of the authenticity of which there can be no doubt); cases where, a child being born at nine months, a second child was delivered some weeks after.—Either the second child was a case of protracted gestation, or it was one of superfoetation. Nor can it be supposed that, in all such cases (and they are numerous), the uterus was bilobated; for it is curious to re-

mark, that, according to the testimony of two very recent writers, Messrs. Cassan and Dance, who have seen several instances of double uterus, where impregnation took place in both chambers, the pregnancy seldom if ever went its usual course, without serious accident either to the child or the mother. A question was put to me by one of the counsel on the trial already alluded to, which I would put to those who deny the possibility of protracted gestation. "Is there any thing in the idea of protracted gestation—of gestation, for instance, retarded till the 304th day—which is so decidedly at variance with the known laws of nature and the principles of sound physiology, as to preclude all possibility of such an occurrence? In other words, is nature so invariably uniform that no deviation from the more ordinary course of uterogestation can ever take place?"

So far from this being the case, we may at once adopt the opposite conclusion, from analogy and observations made on other classes of animals susceptible of direct experiments, which have corroborated the possibility of protracted gestation. The fact is, that it is an error to assert that nature is invariably uniform in her works. Nature is no such thing. She is consistent with herself on every occasion, but not always uniform. Without looking farther than the very subject before us for illustrations, do we not see the greatest difference in the first appearance of menstruation in young women, and their susceptibility of impregnation; in the development of their breasts, and their coming to the age of puberty?

Do we not see every day that some women will bear children within the first year of their marriage, while others, under apparently similar circumstances, have no children until the second or third year, or later, or not at all? Is it not proved by facts, that some married women will bring forth perfect children at eight months invariably? I attend a lady who is in that condition in all her pregnancies; and if nature sends a child forth a month before what is generally considered the ordinary period of gestation, what is there in the converse state that renders it impossible? Nature, in animal as in vegetable life, brings forth the fruit of impregnation when perfectly mature and well organized, without any reference to calcu-

dars or the artificial divisions of time made by men. If we look to domestic animals, the possibility of protracted gestation cannot for an instant be doubted.

So much for physiology and analogy being in favour of the possibility of protracted gestation; the one negatively, the other positively. We have farther in support of such a proposition an overwhelming host of authorities of the highest character.

I will not trouble the society with the enumeration of these authorities, but it may be stated that they are divided into, 1st, authorities who relate cases of protracted gestation occurring in their own practice; 2dly, into those authorities who vouch for the accuracy of cases related by living and contemporary practitioners; 3dly, writers on physiology and medical jurisprudence, who adopt the affirmative question after mature examination, as to the occurrence of many cases of retarded gestation.

Among the older authors more worthy of faith are—Hostius, Sylvius, the celebrated Harvey—a host in matters concerning generation, Mauriceau, Levret, Lietaud, Heyster, Delignac, La Cloture, Benedictus, Petit, Smellie, and Hunter.

Among the more modern are—Oslander, Forderé, Schneider, Lentosseit, Sprengel, Adelon, Bardt, Capuron, Orfila, Burns, Desormeaux, Dr. Dewees, and Dr. Hamilton, of Edinburgh. My colleague, Dr. Merriman, has actually published a table shewing how often, in his experience, the assumed *ultimum tempus* of 280 days was deviated from, either by anticipated births, or protracted gestation. Of the latter, 22 children were born in the 41st week after the menstrual intermission; 15 in the 42d week; 10 in the 43d week; 4 in the 44th week. Dr. Merriman also asserts that upon a few occasions the period of delivery, dating from the last appearance of the menses, exceeded 308 days, and he relates three cases at length.

I know, sir, that it has been asserted on a recent occasion by an eminent accoucheur, that all written authorities, however high, are nothing to him compared to his own experience, if that experience be negative to their statements; but in that case, what will his own printed authority hereafter be worth in the opinion of those men who are to

come, or of those who are now in the possession of facts gainsaying his experience of *twenty cases*? Is not the testimony of any one author whom I have mentioned, founded on *his* own experience, fully as valuable as that of this sceptical physician? These are *ineptiæ scholasticæ* unworthy of the importance of the subject so treated.

But what imports most in proving the possibility of protracted gestation, is the knowledge that legislators of various nations have assented to the legitimacy of children born considerably beyond the *ultimum tempus*, laid down by my friend Dr. Ch. Clarke, as inevitable.

Without going back to obscure times and laws, but looking nearer us, we find that the Scotch law considers a child legitimate who is born within ten months, that is, upon any day of a whole month after the completion of the *ninth* or more ordinary period, so that gestation protracted to 290 days and upwards is possible, according to the Scotch law.

In another case, the legitimacy of a child born in wedlock during the temporary absence of the husband from his wife, and born 10 days beyond 9 calendar months, was decreed unanimously by all the Scotch judges, and confirmed by the House of Lords and the declaration of Lord Eldon. The fact is, that the principle of the possibility of protracted gestation, has, in almost every case which has come before the House of Lords, been admitted and upheld; and if, in a recent case, the decision was against the party claiming to be legitimate, although born 304 days after intercourse between the father and mother, it was owing to peculiar circumstances of a *moral* nature, and not because the possibility of such a principle was doubted. That principle was left undecided. Many of the decisions of the courts in this country during Lord Coke's lifetime, allow forty weeks and *ten* days as a possible period of gestation.

The Code Napoleon says, that the legitimacy of a child born 300 days after all possible access of the parties, may be disputed, consequently it is not questioned before the 300th day, and even then it is not said that legitimacy is impossible, but open to be questioned or doubted. The modern laws of France, therefore, admit the possibility of protracted gestation.

The Frederician Code of Prussia goes even farther, for it does not absolutely declare illegitimate a child born in the *eleventh* month, although it attaches such conditions to prove legitimacy under that circumstance, as to render it almost unattainable; but then it is the *eleventh* month, or 330 days.

Will you permit me to add my humble opinion in favour of the possibility of protracted gestation to the authorities already mentioned; and in order that the society may know whether my statements are well founded or not, I will trouble them with a few details as to the mode in which I obtain my information.

For the last thirteen years I have had the honor of acting as physician-accoucheur to the Westminster General Dispensary; I have moreover belonged to the Benevolent Lying-in Institution for seven years in the same capacity. All patients in a state of pregnancy who seek relief at those institutions, must of necessity come before me. Their number amounts at present to upwards of twenty thousand; but even so large a number of cases would be a sterile source of information, had I not with industry and diligence, in which I have often been seconded by able pupils and other medical persons, endeavoured to investigate, I will not say all, but a large proportion of those cases, and to record the information thus obtained. These investigations of each individual case, and the results arising therefrom, are committed to registers, which I call analytical, and which I first established on being appointed to the public institutions I have mentioned. The members of the society will, I trust, permit me to enumerate the points thus registered, respecting which certain questions and certain information are thus obtained. They are as follow:—

1. Name
2. Age
3. Residence
4. Date of admission.
5. At whose recommendation admitted.
6. The cause of admission, if other than pregnancy.
7. By what midwife or medical gentleman attended in her confinement.
8. Whether single or married.
9. How long married.
10. How long married before she bore children.

11. Profession of the husband.
12. Expected period of confinement.
13. Date of the quickening.
14. How long has menstruation ceased, or whether menstruation or any coloured secretion in lieu of it, exists.
15. Whether the woman was suckling at the time of falling with child.
16. Number of children she has borne—alive or still-born at the time of birth.
17. How many of those are alive now, and in what state of health.
18. If any died—what number, at what age, and from what cause.
19. Statement of children who have had the natural, the inoculated, or the vaccine pox.
20. How many times has the party miscarried—at 3, 6, or more months.
21. How many of these were in succession.
22. Presumed or ascertained cause of the miscarriage.
23. Whether any live child had been born previous to any miscarriage.
24. The nature of the labours—divided into active or without art, passive or with the assistance of art, distinguishing the manual from the instrumental.
25. Whether the pregnant woman be subject to any habitual disease, either independent of or dependent on pregnancy.
26. (Lastly) General Observations.

I shall not stop to point out to the society the many curious and important deductions which may be drawn from so enlarged a series of inquiries, but simply state that with such data, properly and carefully collected, and personally inquired into, a medical man may venture to form an opinion respecting any question which may be illustrated by such means. From so vast a source of information then, I have drawn facts which leave no doubt on my mind that protracted gestation is possible. The cases which I more particularly selected, on a former occasion, in support of this opinion, were so chosen (out of many others) because in those particular cases the parties were living, and might be called; they were cases where, reckoning from the last day of the lunar month immediately

succeeding the last appearance of the menses, a lapse of time took place to the day of labour equal to

292 days.
298 —
299 —
302 —
313 —
317 —
324 —

A lady, whom I attended this year, living with her husband, and who, when not pregnant, has never once been irregular in her menses, calculated the beginning of her last pregnancy from the middle of the 28 days which elapsed between the last time she had menstruated, and the succeeding period when she ought to have menstruated, but did not; and she fixed upon the conclusion of *ten* calendar months for the day of her confinement. She proved perfectly correct. On my asking the reason of such an unusually protracted period, she assured me that all her other children, three in number, were born after a similar interval. True it is that conception, instead of taking place in the middle of the first lunar period subsequent to the last menstruation, might have taken place at the very end of it, and in that case the interval of retardation would only be two, instead of four weeks. Still the possibility of protracted gestation would be equally made out. On the other hand, who shall say that impregnation may not have taken place on the very day after the last menstruation, and thus add two weeks more to the interval originally allowed and calculated upon by the party?

I observed, sir, in the early part of my address, that the *third* branch of this question is the most thorny, and so must every question which, involving interests of the first magnitude, demands of being not only physically, but legally proved.

Unfortunately, what is legally to be proved is not always what can be *physically* proved. Thus in the cases of protracted gestation which I adduced on the trial before the House of Peers, as coming within my own knowledge, there was no disputing the facts entered on my register. They fully bore out the protracted gestation; but then the lawyers required that the hand-writing of every part should be sworn to by the

persons who wrote the entries; and as these were made by several pupils, scattered in various parts of the country, and time was not allowed to summon them, the evidence and the facts were quashed: but is nature to be silenced and turned aside by gentlemen of the long robe; or by cavils, or artificial distraction in human evidence? No. We will continue to believe natural what we observe in nature; be it possible or not to prove (according to certain legal forms, and to human judges liable to err in judgment) that that which we have observed is positively *true*.

I will instance one mode in which it was attempted to invalidate the testimony of the advocates of nature, and the supporters of the possibility of her occasionally deviating from ordinary laws. The Attorney-General (now Lord Chancellor of England) said, "I have satisfied you, my Lords, that not the slightest degree of reliance can be placed upon conclusions formed upon the representation given by the females themselves respecting the reality of protracted gestation." Yet his colleague, the Solicitor-General (in endeavouring to enforce the importance of Dr. Clarke's evidence, who had asserted that his reasons for firmly believing protracted gestation to be impossible, were founded on about twenty cases which had come to his knowledge, where the time could be accurately defined, and that time was forty weeks), declared that the doctor's testimony must be *infallible, because the information upon which the first day of gestation was ascertained, was given by the females themselves*. So that we are to believe the parties on the one hand, and disbelieve them on the other, according as their declarations answer or not the purpose of the lawyer's argumentation. The thing is too absurd. Fortunately, nature has its laws and its exceptions, and these are both independent of forensic cavil.

Coming, however, to something like nearer proofs of the reality of protracted gestation, I would first remind the Society of the positive experiments made by Tessier on animals; and then allude to positive facts, referable to the human species, amounting almost to experiments proving the same thing, as related by Dr. Hamilton, of Edinburgh, Dr. Dewees, of America, Pro-

fessor Desormeaux, and of Professor Velpeau, in a Memoir which that gentleman published in August last, and which was, by a singular coincidence, only this afternoon put into my hands.

All these cases are very strong, and I know not how those who deny, upon their own authority, the possibility of protracted gestation, can dispute the authority of persons of equal respectability, and, to say the least, of not inferior abilities.

This is the book I have just now alluded to; and in it I find, under the head of what the author calls *Naissances Tardives*, besides the enumeration of cases already known to the profession of protracted gestation, two strong instances of that occurrence related by Madame Borvin, a female practitioner in midwifery; of whom it will be sufficient to say, that, for character, station of life, education, experience, and respectability, she is as different from the woman we call midwife in this country, as any two dissimilar things can be. She was many years attached to the Maternité; and no medical man of eminence is there in Paris who would not vouch for the accuracy of what that lady says. Well, then, Mad. Borvin relates the case of a young lady, æt. 27, who became pregnant within the five first days of August; immediately after which she went into the country, where she experienced the usual symptoms of pregnancy, and remained a whole month without the possibility of seeing her husband. At the expiration of nine months, symptoms of labour came on, and Mad. Borvin was sent for; but these symptoms vanished, and parturition did not actually take place until the 16th of May of the present year, making an interval of one month and eleven days after the *ultimum tempus*. Now, sir, the advocates of the other side of the question will instantly damn this lady's reputation, by stating that the case is one in which a married woman played false to her husband during his absence; but Mad. Borvin, meeting them on this ground, has taken care to tell us that the "severity of the lady's principles of religion and morality" leave no shadow of suspicion for such an illiberal supposition.

The other case is also strong, and can only be overturned by the same illiberal suspicion of the honesty of the mother; but Madame Borvin says on this point,

"Cette dame est parfaitement connue de moi, je la vois souvent, et je suis assez sure de ses habitudes et de ses principes pour garantir l'exactitude de cette observation." The case is shortly this: a lady, aged 30, having three children, miscarried four successive times, and became pregnant for the 8th time on the 9th of July, 1828, when every symptom of impregnation supervened. The husband absented himself during four months; on his return, gestation appeared visibly advanced, and the abdomen large. Mad. Borvin had occasion to examine her at this time, and felt convinced she was half gone. At nine months, symptoms of labour came on, but ceased not long after; nor did they return until the 1st May, 1829, twenty-two days after the *ultimum tempus* fixed by man, and not by nature.

Dr. Velpeau has also recorded two new instances, on the authority of Albert, a German physician. Another case by Derenx, a very extensive practitioner of midwifery, in Paris; and a fourth by Dubois. Lastly, he relates a case which occurred in his own practice, and which, even with the gratuitous assumption of the dishonesty of the mother, and granting that medical men may be mistaken in regard to the first signs of pregnancy, leaves no doubt of the labour having been protracted to the 300th day after conception. But I must refer the members to the Memoir itself, which they will find in the number for August, 1829, of the *Nouvelle Bibliotheque Medicale*.

The paper I hold in my hand, sir, is a copy of a letter from Dr. Hamilton, jun. of Edinburgh, the celebrated obstetrician, dated June 12th, 1825. I will not take up the time of the Society in reading the document (to which any gentleman is welcome to refer after the meeting), but I will content myself with stating, that Dr. Hamilton admits the possibility of that which I contend for—protracted gestation—first, on his own personal knowledge of facts that have passed under his own observation; and secondly, on the knowledge of well-authenticated cases that have occurred to others.

Out of the many other authorities whose names I have mentioned, I will purposely confine myself to that of Desormeaux, the professor of midwifery in the university of Paris, and a

gentleman of the strictest honour; as well as to that of Dr. Dewees, of America, an eminent accoucheur, with whose writings and high reputation the profession in this country must be familiar. With the narrative of the cases of protracted gestation taken from their writings, I shall conclude my observations this evening.

Professor Desormeaux says, a lady, the mother of three children, became insane. Her physician considered that childbearing might have a beneficial influence on the mental disease, and permitted the husband to visit her, but under condition that it should be only once, and at the distance of three months, in order that if conception took place, there might not be a chance of abortion, from the circumstance of any further intercourse. The physician and attendants made an exact note of the time when the husband was permitted to visit his lady. When, at last, symptoms of pregnancy appeared, the visits were absolutely and totally discontinued. The patient was necessarily watched by the female attendants required for her malady, and was, moreover, a lady of the strictest principles of morality. She was delivered at the termination of nine solar months and a fortnight of a *small* child, and Professor Desormeaux delivered her. This case, I need hardly observe to the society, is of the utmost consequence; first, because it is vouched by two highly respectable physicians, the one an accoucheur of eminence, and both of whom are living; secondly, because of its recent date; thirdly, because the very hour of impregnation was ascertained; and lastly, because the lady being afflicted with a serious malady, had probably her period of gestation retarded by it, a conclusion which might almost be said to be confirmed by the child being unusually small. It is true the retardation of the term was only fifteen days; but it proves that gestation may actually be protracted beyond the pretended and inevitable *ultimum tempus*, and consequently, that the asseveration of those who, without any practical fact to support it, declare that the going even one day beyond the forty weeks is impossible, is refuted by that very nature whose laws they pretend to *define* and *confine*.

Dr. Dewees' case is this:—The husband of a lady was obliged to absent himself from her, in consequence of

embarrassment in his affairs. He returned one night clandestinely, and his solitary visit was only known to his wife, her mother, and Dr. Dewees. The consequence of this visit was conception, and the lady was delivered of a healthy child in nine months and thirteen days after that nocturnal visit.

These, sir, are but few of the many instances I might adduce; still they are of such weight and authenticity that they alone are sufficient to silence any remaining doubt in the breasts of candid and respectable men. Among living practitioners, I have mentioned such a constellation of highly-gifted practitioners that it would be difficult to find their equals, and decidedly impossible to name their superiors. Let that go as a balance against the fact, that the sceptical physician, who denies the possibility of protracted gestation, is a very eminent practitioner.

Having brought to a conclusion what I had to offer to the society on this subject, it remains for me to apologise to the members for having trespassed so long on their attention.

[The following are the documents alluded to by Dr. Granville, containing the opinions of Professor Hamilton.]

Edinburgh, 23, St. Andrew's Square,
June 12th, 1825.

Dear Sir,

* * * *

I have enclosed to you such extracts from my very last lecture on this subject, as may enable you and your law friends to understand my opinion.

In addition to the enclosed, I have to mention a case which, from particular circumstances, I have not thought myself warranted in detailing in my lecture.

A lady residing at some distance from Edinburgh, according to her own admission, at the age of from 35 to 37 became pregnant, passed as she supposed the eleventh menstrual period, and bore with great difficulty a dead child. In due time the same circumstance again happened.

After this second disappointment I was consulted on the case, and I was decidedly of opinion, that although she could afford nourishment and origination to the infant up to the ordinary period, she was incapable of doing so beyond that time. My advice, there-

fore, was, as she had resolved to come to Edinburgh to be under my care, that whenever she should pass the tenth menstrual period by one week, she should allow me to bring on labour in the way I am accustomed to induce premature labour, in cases of narrowness of the pelvis. The result was most fortunate; a very fine living daughter, and it may appear most extraordinary, though it is not less true, that she has again had another child (a boy) born under precisely similar circumstances.

With respect to the case of the Marchioness of Tweeddale, you have been misinformed. After bearing two children, she was left by the medical attendant and midwife, and at the distance of *fifteen hours* bore a third infant. Her constitution received such a shock from flooding, that she eventually died in France.

Believe me to be, dear Sir,

Yours sincerely,

JAMES HAMILTON, Jun.

Extracts from Dr. Hamilton's 17th lecture :—

"Having thus mentioned the facts* by which I conclude that pregnancy is occasionally protracted beyond the more ordinary period of nine calendar months, it may be asked, how long I consider it possible that it may exceed the usual period? To this I reply, that according to my experience, there are not yet sufficient data to establish more than the general principle.

"While I admit the general principle, that the period of pregnancy may be exceeded certainly by three or four weeks, I must agree with the ancient lawyers and judges, that in any particular case the decision must depend upon circumstantial evidence. But while I concede thus far, I should take the liberty to differ from many authorities quoted, particularly the precedents published by the parliaments of France during the seventeenth century. They seem to have proceeded upon the principle admitted by the Roman law, that the character of the woman should decide the question.

"But in matters of this kind we

should err most egregiously if we trusted to character, which is so obvious a proposition that it is scarcely maintained in the present day. In truth, it is to be considered only as one link of the chain.

"Foreign practitioners talk a great deal about the influence of passions of the mind—mode of living—certain diseases during pregnancy—evacuations during the same state, such as blood-letting and purging, in retarding the term of pregnancy; but the result of my experience is in direct contradiction to such ideas.

"I never met with any instance where I could attribute the protraction of pregnancy to passions of the mind, or to evacuations. What I mean, therefore, by circumstantial evidence in any given case, respects the state of the menstrual discharge. Thus, suppose that a woman alleges that she has gone eleven calendar months with child, dating her pregnancy from intercourse on a particular day, if I were a judge I should demand evidence that she had been obstructed from the time of the alleged intercourse; for if she had menstruated after that time, she could not have been pregnant."

That the above may be intelligible, the following extracts from the preceding lecture are added :—

"We are obliged, therefore, to reject the testimony of women themselves, and to be directed in our judgment by other circumstances."

"The principal of these is the duration of the menstrual obstruction."

"A woman cannot fall with child during menstruation, but she may immediately after that period, or immediately before the next expected return."

"If, therefore, the tenth menstrual period be ever exceeded, there is evidence that the woman may have gone above nine calendar months."

"Now, Dr. Young, my father's predecessor in this chair, in his note-book here before me, says expressly, that he has known women go to the day of the tenth eruption, but never beyond that."

"But the result of my experience has been different: in one case, many years ago, the lady exceeded the tenth revolution by twelve days. Another lady exceeded it by sixteen days, and another by twenty-four days. This latter patient menstruated on the 1st August, and was not delivered till the

* One of the most remarkable which Dr. Hamilton mentions, and for the accuracy of which he vouches, is the following :—

"Mrs. —, menstruated Nov. 1800, and might have been with child that week, say Nov. 5th. She was not delivered till Sept. 16th, 1801, being seven days past the eleventh menstrual period."

28th June. Another lady, the mother of a large family, exceeded her period by above a fortnight, on the 4th March, when her husband went to England, where he resided for some months; but she was not delivered till the 6th of December."

"Of the truth of those facts there can be no doubt, and you see that they tend more to decide this question than cases founded upon the absence of the husband, or in the instances of illegitimate pregnancy, upon the date of the connexion of the parties."

Dr. FRANCIS RAMSBOTHAM availed himself of the kind invitation just given to visitors by the President, to offer a few remarks on the subject before the Society, as no member seemed inclined to reply to Dr. Granville's observations. He thought that nothing which Dr. Granville had advanced that evening, nor any thing indeed that had previously come before the public, proved satisfactorily that *human* gestation could be prolonged to any extent. The facts brought forward by Tessier indeed, to which Dr. Granville had alluded, were exceedingly valuable, and conclusive with regard to *comparative* gestation, and analogical reasoning would lead us to infer from them that *human* gestation also might possibly be occasionally somewhat protracted; but he contended that no case had been made out of decided prolonged gestation in the *human* subject. The opinions which were elicited on the late trial, regarding the Gardner peerage, were exceedingly valuable, as being those of the most eminent men in the profession; and it was strange to see how much opposed the two parties were to each other in their sentiments. On the one hand, Dr. Clarke, Dr. D. Davis, Dr. Gooch, and others, believed human gestation never to exceed beyond a day or two the nine calendar months; while Dr. Merriman, Dr. Granville, Dr. Blundell, Dr. Elliotson, and some other gentlemen of eminence, were ranged on the side of more lengthened protraction. Some *females*, however, were examined on that occasion, who believed that they themselves had exceeded the ordinary limits; but their calculations were made in a very vague manner, and from very uncertain data. On reading the evidence, only one case struck his mind as being strong,—that of Mrs. Mitchell, who calculated from the absence of her husband.

He was purser to his Majesty's ship *Galatæa*, and she said he left her on June 6th, 1798, and did not return, yet she was not delivered till April the 11th following, making a period of ten months and five days; but how was her statement borne out in the sequel? It was proved by a clerk from the Navy-office, that the *Galatæa* was moored in Plymouth Sound from May 5th to July 9th of that same year. Mr. Mitchell was purser of the vessel, and it was shewn, by the muster-rolls and his own signatures, that he never left his ship during any part of the time she was lying there. From these remarks it might be gathered, that he was opposed to the protraction of human gestation. True *utero-gestation* he believed indeed to be fixed, definite, and unvarying; but there is a space, a period of time, between conception and the lodgment of the ovum in the uterus. It must be remembered that on impregnation taking place, the fimbriated extremity of the fallopian tube seizes the external surface of the ovary, and squeezes from it whatever the female supplies towards the formation of the new being. Being received into the tube, the impregnated ovum travels along the canal until it is deposited in the uterine cavity. It is generally supposed that from seventeen to twenty days are occupied in this transit: but is the time during which it is passing along the tube always the same? He believed not: he thought it varied considerably from a few days to above a month, and he thought if we admitted this variation in time during the transit of the ovum, that admission would explain all the deviations from the common course of events, which we generally see in human pregnancy. That the ovum remains some time in the tube he inferred from dissections of animals; for in the rabbit, whose period of gestation is thirty days, the ovum was not found in the uterus until the sixth day, according to Haighton's observations, and the fourth day according to Cruickshank's. In the sheep too, whose ordinary time is five months, Haller did not find the ovum in the uterus until the seventeenth day. If he were asked how is life preserved to the ovum during this time, how is it nourished, and whether it increases in size; he would say, it does not increase, because it cannot be attached to the mother by any vascular connexion; if it were, the case would

become one of *extra uterine* gestation, as the ovum would be fixed to one spot, and never could be propelled into the uterus; life is continued to it, although not attached to its parent's body, in the same manner as life is continued to an egg for many months after it has been laid, and also to a seed for years after it has left its parent plant. Eggs have been hatched after a voyage to the East Indies and back; and we are told by Ray that melon-seeds kept forty years produce better plants than when fresh. But some few dissections also in the human subject would bear him out in the idea that the time of transit of the ovum is not always of the same duration.

In the second volume of the *Transactions of a Society for promoting Medical and Surgical Knowledge*, there is an accurate description, given by Mr. Ogle, of a dissection, by John Hunter, of the body of a woman who died more than a month after impregnation, in which no ovum could be detected in the uterus. Mr. Burns, in three instances, within the month, could not find an ovum in the uterus: Haller says he never detected any before the seventeenth day; and Blumenbach thinks the ovum is not formed for a fortnight, when he believes the *nissus formativus* comes into operation. On the contrary, in the volume of the *Philosophical Transactions*, published in 1817, there is a case, by Sir E. Home, of the dissection of an unmarried woman, who died on the eight day after connexion, and in whose uterus an ovum was discovered perfectly formed, of the same size as Hunter describes them at the month. Sir E. was assisted in his microscopical observations by Mr. Bauer, of Kew, and has given magnified drawings of the appearance of the ovum. If we consider this case to be relied on, we have a variation of three weeks in the different instances, and this will be sufficient to explain all the variations he has ever heard of entitled to credit.

Dr. A. T. Thomson stated that, in his opinion, there existed no reason for supposing that nature might not deviate from her laws, as far as regards the period of utero-gestation; since, in every other respect, we find deviations. He was anxious to know whether any correct information had yet been obtained respecting the immediate cause of parturition; for if this is connected with states of the system, which are liable to

variation, from individual differences of either function or structure, it is more wonderful that the period is so constant, than that occasional variations should occur. In reply to Dr. Ramsbotham, who contended that the period of utero-gestation is fixed, and that any apparent difference arose from variations between the time of conception and the introduction of the ovum into the uterus; he maintained that no inference could be derived from his arguments against Dr. Granville's position, as it is of little consequence to the legal part of the question, which is the point at issue, whether the length of time between conception is attributable to any difference in the period that the ovum takes to travel from the ovarium to the uterus, or in the time that it remains in the uterus prior to its expulsion. If the whole time, in the majority of cases, be 280 days, we may conclude this to be the natural period; but if cases, that can be verified, have occurred in which this period was extended to 290 and 300 days, then we had a right to infer that there might exist circumstances connected with certain individuals, which would either shorten or protract that period. In a legal point of view, this is a fact of great importance; the establishment of it is connected with moral and religious conduct, of vital interest to civilized society; and, in his opinion, no case had yet been made out to invalidate the conclusion arrived at by the proposer of the question—that protracted utero-gestation may really take place, and has frequently occurred.

Dr. Locock gave it as his opinion that in all cases of supposed protracted pregnancy the difficulty was to get at the two ends of the chain; the date of parturition was easily ascertained, but how was it ever possible to determine the exact date of conception, without risk of meeting with wilful misrepresentation or involuntary mistake? One striking proof of nature having a fixed rule was the fact, that in cases of extra-uterine foetation, where the child is so situated that parturition at the nine months' end cannot take place, the child does not go on increasing in its unusual situation, but *dies*. Foetal life seems to cease at a certain point; and this point is the same at which all people agree to fix the natural period of utero-gestation. Even in married women, where there may be no motive for deception, we all

know how liable we are to be misled : they are often fancying that they are pregnant ; they increase in size, the menses stop ; they even think they feel the motions of the child ; but it all goes off again. In the same way they cease to menstruate from ill health for a month or two, and as they feel sick and unwell, they think themselves pregnant. The ill health ceases, and just as the uterine functions are about to be restored, they fall with child ; and hence they think they remain pregnant ten or eleven months, when, in fact, the real pregnancy did not begin till one or two months after they had supposed. It is well known that women may thus become pregnant, for they have even done so before they have ever menstruated at all, as is seen in a case related by Sir E. Home in the Philosophical Transactions. Dr. L. did not deny the possibility of protracted utero-gestation ; he would be presumptuous to do so, when it had been proved to occur in the lower order of animals, but he had never met with a case in his own knowledge in which he could not explain the circumstances in the way he had suggested. All such supposed deviations from nature's rules should be received with the utmost caution and suspicion. Dr. L. related a case reported to him by the agents in the Gardner Peerage case, which was confirmed by very strong testimony :—A naval officer's wife was confined ten months after he had left her. By the advice of a medical man, (the late Dr. Hopkins,) he tried an experiment to prove whether she had, as might have been the case, some peculiarity of constitution ; and if so, the same ten months' pregnancy would of course occur a second time. A single cohabitation took place, and then the lady was secluded for a time under the most careful surveillance ; in ten months from that time she was delivered, and the naval officer's suspicions of previous infidelity were at once dissipated. When we see what slight moral or physical causes will interrupt a labour already begun, or will suspend the progress of an exanthematous disease, it is fair to suppose that there may exist causes which will occasionally put off the period at which parturition naturally occurs.

Dr. MERRIMAN said that he thought the opinions of honourable, virtuous married women, upon this subject, were

treated with too little consideration. It sometimes happens that women who can have no sinister motive, or any interest to deceive themselves, their husbands, or their doctors, express a belief that they have exceeded the usual duration of pregnancy. Some circumstances, about which a medical man cannot always very minutely inquire from a virtuous woman, lead them to date their conception from a particular day, and their pregnancy extends beyond 280 days from that particular occasion, and they therefore think that they have passed the usual period of gestation. Now these are often women who have had several children, women of good education and information, very competent to form a correct judgment. But the opinions which they have deliberately formed, are slighted, and the accuracy of their calculations are denied. And why ? because it is assumed to be impossible for the law of nature in this respect to be violated, and therefore it is asserted that their calculation cannot be true. If the question is asked, why it cannot be true, the only answer is, that very convincing one,—"because it cannot."

But it is thought that certain evidences, which have been confidentially communicated to different physicians, set this important point at rest. One accoucheur has met with ten cases, another with five, another with twenty, in which the ladies—unmarried women, have once, and once only, been so unfortunate as to make a slip ; and in no one of these cases has the period of 280 days from the day of the accident been exceeded. It should be borne in mind, however, that there is one case upon record where intercourse took place once, and once only, and the period of 280 days was exceeded. This may be found in the trial of a man who was prosecuted for the seduction of the plaintiff's daughter ; and in giving evidence, under her solemn oath, she swore that the only time she ever had connexion with the defendant was on the 8th of January ; that it was a Sunday ; that the intercourse took place about eight o'clock in the evening ; and other circumstances are enumerated to fix the exact time. She went on to swear that the day of her delivery was the 18th of October, which, including the day of ~~concept~~ and that of delivery. Surely this evidence

as that given confidentially to a physician; and, according to this statement, the impossibility of exceeding 280 days of utero-gestation was completely disproved.

Mr. NORTH was of opinion, that the occurrence of protracted gestation was less difficult to comprehend than had been generally imagined. Although it might be impossible satisfactorily to explain the nature of the various causes which so frequently induced premature delivery, the existence of such causes could not be denied, and Mr. N. imagined that the opposite condition of the mother, which led to too early delivery, might fairly be supposed to procrastinate the ordinary period of utero-gestation. He was unwilling to enter into any speculation upon the subject. Upon such a question it was difficult to obtain satisfactory proofs in the affirmative, but he considered the following case in itself a sufficient proof that protracted gestation occasionally occurred. A young lady, about 16 years of age, had some years ago been under Mr. North's care. He had reason to believe she was afflicted with some uterine disease, and upon examination it was found that the os uteri was swollen and excessively tender; the cervix preternaturally hard, having almost the feel of schirrus. In a year afterwards this lady married, but she suffered so much pain from sexual intercourse, that she was obliged to separate from her husband's bed, after having lived with him but one week. It soon became evident that she was pregnant, and in 304 days from the third day of her marriage she was delivered of a son. Mr. North doubted the utility of the request which one gentleman had made, that Dr. Granville should explain *how* protracted gestation happened. He thought it would be just as impossible to explain why nature sometimes deviated from her usual course in a still more extraordinary manner, and united two boys together, or produced a child with two heads and one body. Mr. North concluded by observing, that if no exceptions happened to the ordinary period of utero-gestation, it was the only process or law of nature that was not occasionally deviated from.

[The hour having now expired, it was agreed to adjourn the discussion till next meeting—*this evening.*]

IMPOSING RESTRAINT ON LUNATICS.

To the Editor of the London Medical Gazette.

10, Montague Street,
December 7, 1829.

SIR,

No one entertains a higher estimate of the value of fair criticism than I profess. I am also fully sensible how incompetent we all are to judge of its correctness, when self is concerned; I therefore decline offering any observations upon your reasoning and conclusions in the last Number of the Medical Gazette on my letter to the Editor of *The Times* of the 26th ult.

You must allow me, however, the liberty of expressing my opinion, that it is nothing short of combining with popular clamour to prejudge a professional man, who rests his defence in the very letter criticised, on circumstances he declares he cannot divulge without violating professional confidence.

Surely, Mr. Editor, it would have looked more like impartiality, supposing that you felt yourself imperatively called upon to bring into immediate discussion a subject, the whole of which is still unpublished, to have given my letter entire, as printed in *The Times*. Your readers then would have had an opportunity of deciding for themselves on my conduct, as far as it is explained. Your critical remarks might have followed, and have been perhaps better understood. As it is, you select only certain passages, and separately comment upon them, which, when read with their context, may bear a very different interpretation.

If you mean to do me justice, as I do not doubt, I must request you to print my letter in the next Number of your Journal, as it is inserted in *The Times*.

I am, Sir,

Your obedient humble Servant,

G. MAN BURROWS.

[Our *only* motive for not having inserted the letter of Dr. Burrows before was the belief that it had already been made sufficiently public, from the extensive circulation of the paper in which it appeared: that it arose from no hostile feeling, he must be convinced, from our having given place, unasked, to his first "explanation." We now subjoin the letter to which he alludes; and we do so, not because we

think it will alter the opinion of our readers on the subject, even if they do not happen to have seen it already, but because it might otherwise be supposed by Dr. Burrows that we had not dealt fairly by him.]

To the Editor of the Times.

Sir,

After my appeal to the public on the 7th instant, I flattered myself that judgment on all parties concerned in the case of Mr. Freeman Anderdon would have been suspended, and further animadversion reserved till the pending judicial proceedings fully disclosed the particulars. Nevertheless, it appears that neither a sense of equity, nor respect for private character, avails, when popular clamour is excited. Thus goaded, a man must reply or suffer odium.

Regard for the feelings of an honourable family, might probably still have induced me to endure in silence the calumnies poured upon me. But when I find so influential a journal as *The Times*, checked by no consideration, open its columns to the rhapsodies of an obvious madman, and thus give them all the weight of sober truths, I am aware that no reputation, however fair, can resist the consequent unfavourable impression. Surely there was, in the letter which you inserted from Mr. James Wells, of Sudbury, to Mr. Peel, sufficient to create a suspicion of the soundness of the writer's intellects. Had you made any inquiry before you published his letter, you would have learned that the said Mr. James Wells was found a lunatic, under a commission issued a few years ago, and which is not yet superseded.

How the Secretary of State could have been imposed upon by such a frantic effusion, as to condescend to notice it; and why his secretary, in his answer, should introduce my name, which is not mentioned in the letter, I cannot more readily comprehend than the reason for its finding a place in *The Times*. However, this is not the first time that the cunning lunatic has made easy dupes of wise men.

Thus assailed, I must claim the privilege of space for further observations.

To publish a detail of the overt acts of insanity, upon a knowledge of which I judged Mr. Freeman Anderdon to be of unsound mind, neither the vulgar taste for tales of madness, nor even my own justification, shall induce me to do, in violation of professional confidence.

The particulars of his case are submitted to those who have authority to inspect them, and time must disclose them. I unequivocally admit, that medical examination of a suspected or alleged lunatic should always precede, where it is possible, his being placed under restraint. But many cases must, and do occur, where that preliminary is wholly impossible. The case of Mr. F.

Anderdon is precisely one of that description. The unsettled, wandering habits of this gentleman presented an insuperable obstacle to an interview with him; and it was represented to me, that to preserve him from utter ruin, he must be placed under restraint by the following evening.

Some of the eccentricities in the person and dress of Mr. F. Anderdon, but by no means all of them, have been described in the police report. But these eccentricities are not confined to external appearances; and as they are notorious, and relevant, I may give publicity to them.

Although still a young man, this gentleman has, for several years, without any known cause, estranged himself from his highly respectable relations and connexions, and, shunning all human association, took up his abode in a very obscure disreputable part of Lambeth-marsh. There he resides, in a small, miserable, dilapidated house, with broken windows, and a few iron bars across the lower one. It may be inferred that he has few visitors, for neither the gate of the fore-court, nor house-door, has bell or knocker. He lives a solitary being, without any servant or inmate. His meals he takes at cook-shops, where the lower orders resort. No one knows when he goes out or will return, or can give any account of his movements.

Let me here ask, how an interview and medical examination was to be obtained within twenty-four hours with such a character?

Had he, by chance, been found at home, murder might have been the consequence of intrusion; for he was said to be likely to make a desperate resistance, and was well known to keep loaded fire-arms at hand.

With a most anxious desire for me to obtain an interview with their brother before restraint was imposed on his actions, Messrs. O. and J. Anderdon undertook to employ themselves next morning in ascertaining if any way presented of effecting it. They met the following afternoon at my house, in Montague-street, by appointment, and reported the failure of their endeavours. No alternative being left, instructions were then given to two of my attendants, who had been ordered to meet those gentlemen, and they were directed as to the best and safest probable mode of executing their duty. Their directions were, to exercise every delicacy and caution towards Mr. F. Anderdon; to watch his return home; to accost him at his gate before he got in doors; to tell him candidly for what object they came; and to use no violence, but endeavour to persuade him to permit their continuance with him in his own house till the following morning.

And here I shall take leave to correct one of the numerous falsehoods circulated,—viz. that the domestic privacy of Mr. F. An-

derdon was violently broken in upon by the entrance of two keepers into the room where he was sitting. The fact is, they never crossed his threshold, or entered his house in any manner. Indeed, how were they to gain such admission, when no one, according to the account published of the transaction, was in his house except himself, to open the door? Were the men likely to effect an entrance secretly, at the risk of being shot? Mr. F. Anderdon still being at the gate of his fore-court, immediately cried out for aid; and the keepers were instantly seized, never having had charge of him.

That the keepers entirely conformed to the humane directions they received, that gentleman himself acknowledged openly at the police-office, by shaking hands with one of them, and thanking them both for their civil and proper behaviour; yet these agents, who so well conducted themselves in executing one of the most delicate, and often dangerous, duties that can be undertaken, were hand-cuffed like felons, thrust into the black hole of the watchhouse, with the vilest wretches, denied their repeated requests for pen, ink, and paper, to communicate their situation, and were thus kept imprisoned for sixteen hours, and were then dismissed by a magistrate for want of any charge against them!

Some have imagined that I signed a certificate to convey Mr. F. Anderdon to an asylum for lunatics. This is a wilful error. The sole object intended and expressed was to keep him in his own house, being the only practical means of insuring such a medical examination as was necessary to be instituted previous to any application for a commission of inquiry into the state of his mind.

Others conceive, that an opinion on the sanity or insanity of a person's mind ought not to be formed and decided upon any representations at all. Yet, from the history of a case we can often draw the clearest inference, while a personal examination without it will elicit nothing.

In our courts of judicature medical opinions are permitted to be received respecting the soundness or unsoundness of a mind, though the witness may never have seen the lunatic.

Dr. Monro and I attended at a trial ("Farmer v. Field"), which occupied two days, at the last Surrey assizes, where, after hearing the evidence on both sides, we were examined as to the soundness of an individual's mind at a specific period, when he had been visited by neither of us. I remember a more remarkable instance in point. At a trial ("the King v. Hibbert") before Lord Chief Justice Tenterden, to traverse a commission of lunacy, a medical gentleman, eminent for his knowledge in mental affections, was attending merely from

curiosity, and he was put into the witness-box by the present Attorney-General, and desired to give his opinion from the evidence he had heard in Court, never having examined the lunatic whether he was of sound or unsound mind; and that opinion, so delivered, had of course an influence with the jury in consigning him to all the degrading consequences of a verdict of unsound mind.

I hold myself blameless for acting on the evidence adduced by the Messrs. Anderdon of their brother's malady; and so, in candour and justice, ought every one till they learn the nature of the evidence I received. They were known to me to be gentlemen of the highest character and respectability; and with one of them I had been personally acquainted several years.

Your correspondent, Mr. Browne, clerk to the metropolitan commissioners in lunacy,—in an answer, somewhat gratuitous perhaps, to an anonymous querist in *The Times* of the 10th instant,—gives an interpretation to the act 9 Geo. IV. cap. 41, in reference, I presume, to Mr. F. Anderdon's case, very different indeed to my reading of it. I have not had time to ascertain which of us is right. But if I have acted in contravention of any of its provisions in this case, I have done so unintentionally, and repeatedly; and in this I have erred in common with other medical practitioners. However this may be, I do not, upon a review of the peculiar circumstances of the case in question, see in what way I could have acted otherwise. Restraint, *i. e.* mere supervision, is not coercion, nor does it imply removal.

If it be enacted, that before an insane person can be placed under any restraint, as Mr. Browne interprets, an order must be first obtained from a relation, and likewise a certificate of insanity, signed by two medical men after separate examinations; what may not be the dreadful consequences! Suppose a person is seized with furious delirium, or a sudden paroxysm of mania,—a common occurrence,—are the parties suffering or in danger from his fury to remain passive, and not put him under any restraint till a relation orders it, and two medical men, who may not be easily found, sanction it by distinct visits and signatures, lest they should incur the penalties of the law, or public obloquy?

The new act for the care of the insane, as a whole, is an excellent measure; but it is not within the scope of legislation to frame an enactment to meet all the varieties and modifications of so protean a malady as mental derangement.

If, by the provisions of it, power be really given to prevent any restraint being imposed, except under the regulations just referred to, and which leave no latitude for acting according to the nature of the case, then is an able writer on medical juris-

prudence correct in saying, that "the enactment will be oppressive in its operation, and incompetent to meet the exigencies of intellectual calamity,—an act calculated to confirm and aggravate the horrors of madness, to invite suicide, and multiply murder." What has resulted from the case of Mr. F. Anderdon proves the serious and discouraging fact that a character, hitherto unimpeached, cannot secure a professional man the credit even for good intentions. Without a possible motive more than in common cases, he may be not only suspected, but accused of the worst actions. No one who reflects will deny, that insanity in its characters is dissimilar to every other disease. The ordinary rules which govern us in other afflictions of humanity do not apply in this, but are often reversed. It follows, that the physician who expects successfully to treat it must obey the indications of the moment, and if he sometimes errs in judgment, is it to be wondered at? Besides, each case, perhaps, involves a legal question, and many proceed to a legal investigation, in which the name and conduct of the attending physician is necessarily implicated. No physician, therefore, is so exposed to animadversion, or, from fear of a breach of professional faith, so restricted from defending himself.

Consequently, if the present illiberal system of arraigning and prejudging a physician's conduct from *ex parte* statements be pursued, what man who knows that his reputation is his existence will devote himself to the study and treatment of insanity, when the practice is fraught with such awful responsibilities?

Supported by the consciousness of neither intending nor doing wrong, I confidently look for reparation from those who, in ignorance of the facts, have, through the medium of the press, so distorted the truth.

I am, Sir,

Your obedient servant,

G. MAN BURROWS, M.D.

10, Montague-street, Russell-square,
November 24.

LONDON UNIVERSITY.

To the Editor of the London Medical Gazette.

University of London,
Dec. 8, 1829.

SIR,

In your publication of last Saturday you announce, that "the Council of the University have abandoned all intention of attaching an hospital to that institution."

You have been misinformed, for the

Council have not abandoned their intention of attaching an hospital to the institution.

I request that you will insert this note in your next Number.

I am, Sir,

Your very obedient Servant,

LEONARD HORNER, Warden.

[We have only to say, that we did not insert the paragraph alluded to without such authority as we had reason to believe was good.]

BOOKS RECEIVED FOR REVIEW.

The Properties and Preparation of the Rio Negro Sarsaparilla, and of the Angustura Bark, practically examined. By John Hancock, M.D. Fellow of the Medico-Botanical Society, &c.

Descriptive Catalogue of the Anatomical Museum of the University of Edinburgh.

Auli Cornelii Celsi de re Medica, libri octo, ex reconsione Leonard Targii, interpolationibus tantummode emendatis, curante G. F. Collier, M.D. (Vol. I.); together with an entirely new Translation of the same Author.

De Lingua Anatomica Quaedam et Semiotica. Dissertatio Inauguralis quam Consensu Inclyti Medicorum Ordinis, pro Gradu Doctoris in Medicina et Chirurgia, publice defendet auctor Robert Foriep, Saxo-Vinariensis.

NOTICES.

The great length to which the important discussion on Protracted Gestation has extended, and the anxiety to comply with Dr. Burrows's wish with regard to the insertion of his letter in the present number, must plead our excuse with those gentlemen whose papers are thus unavoidably postponed till next week.

The circumstances above alluded to have also compelled us to omit the letter from "A Professional Friend."

The communications of Mr. Luke—Mr. Bond—Mr. Hoskin—Mr. Koecker—Mr. Smith—Mr. Johnson—Mr. Morley—A Surgeon Apothecary and Man-midwife—Eblanensis—Amicus Justitiae—Dr. Harwood—Jonathan Oldbuck—and Mr. Boyne, have been received.

J. R. M. is probably aware that the letter of "Wintoniensis," in another Journal, is undergoing legal investigation, and that we have on that account declined publishing his letter.

We should have had much pleasure in publishing the letter of "A Member of the Westminster Medical Society," had not we given insertion before the receipt of his paper to one which appeared to us to supersede it.

Mr. B.'s paper next week.

W. WILSON, Printer, 57, Skinner-Street, London.

THE LONDON MEDICAL GAZETTE,

WEEKLY JOURNAL

OF
Medicine and the Collateral Sciences.

SATURDAY, DECEMBER 19, 1829.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

LECTURE XII.

**Recapitulation.—Chronic Abscess—Hectic Fever.*

I spoke to you, gentlemen, in my last lecture of the various cases in which it is necessary to open abscesses, instead of waiting for their natural discharge; and in most of which it is also advisable to open them early, in order to limit the extent of the mischief which suppuration might produce. As I do not know that I enumerated to you accurately, on that occasion, the *whole* of the cases that come under this head, I shall now repeat what I then said, in order to make the catalogue complete.

First.—This mode is necessary where the matter forms deep in the limb, and where the progress to the surface is opposed by strong fasciæ, tendons, or muscles—as in deep suppuration in the fore-arm, in the thigh, in the neck or back, in the palm of the hand or sole of the foot.

Secondly.—Where violent inflammation attacks a part in which there is an abundance of cellular and adipose tissue, such as about the termination of the rectum and the neighbourhood of the anus; and this more particularly when, in addition to the existence of much cellular tissue, which is the seat of inflammation, there are muscles or fasciæ, or other parts over this tissue, which tend to prevent the pus from coming to the surface, as in the formation of matter about the urethra in the male, either in the perineum or behind the scrotum;—in abscesses occurring in the groin, or deep seated in the neck.

Thirdly.—Wherever matter forms in parts of very dense and unyielding texture, or in

those in which there is a very abundant supply of blood-vessels. The hand and fingers exemplify this circumstance.

Fourthly.—In the formation of matter that takes place in the immediate neighbourhood of the great serous cavities or of the joints.

Fifthly.—In those that might interfere with parts which are immediately essential to life—such as the formation of matter about the throat, in the neighbourhood of the larynx, or in the immediate vicinity of the trachea and œsophagus generally.

Sixthly.—In those suppurations which are produced by the injection into the cellular membrane of irritating fluids—such as an extravasation of urine or feces.

Lastly.—In certain cases where it is expedient to prevent an extensive suppuration, on account of the deformity which this might involve, and where the small puncture made at an early period with a cutting instrument will leave a less considerable cicatrix than that which would result if we allowed the matter to come forward so as to produce distention and pointing of the skin. This applies to the formation of abscess about the face.

The pus which is contained in an abscess being excluded from external influence, undergoes no change after it is secreted—no change in composition. It may remain weeks or months, or, I might even say, years in such a situation, and not undergo any of those spontaneous alterations that take place if it is open to the air. Hence, when pus is let out, it has but little odour—that is, it has only a faintish smell. Sometimes, however, we find that the matter which we evacuate has undergone decomposition—that it is putrid—in fact, instead of a white, thick, soft, homogeneous liquid, we let out a dark and stinking fluid, in which there are numerous streaks of black and blue, sometimes mixed with coagula of blood, and excessively offensive to the smell. In some instances the matter presents the ordinary appearance of good well-formed pus,

but yet is very offensive. To the senses there is no other indication of a change except fœtor. Now this is a state observed particularly in abscesses occurring in certain situations. It is noticed very commonly in those that are formed in the neighbourhood of the anus, or near the situation of the large intestines—in those that are formed in the neighbourhood of the male urethra, either in the perineum or about the scrotum—in those that are formed near the entrance of the female organs of generation, as the labia pudendi.

These are situations in which we often meet with the phenomena in question. At the first view you might suppose that some communication existed between these outlets and the cavity of the abscess, and that thus the decomposition might be accounted for; but this is not the case. We find it in instances where we are certain that there has been no communication between the cavity of the abscess and the passages I have mentioned; and in certain instances we do not find this particular character, this decomposition or fœtor of the matter, in abscesses that occur in those situations; it is not a constant occurrence even in the circumstances alluded to. It has been supposed that the presence of coagula in the cavity of the abscess may lead to this decomposition, and that the matter becomes fœtid when portions of blood are mixed with it. Now I have sometimes seen suppuration taking place in hemorrhoids about the anus, and there the matter that is deposited becomes mixed with coagula of blood, and in these instances such matter has been excessively offensive; but in certain cases we find the same occurrence where the abscess does not form in the particular situation I have now mentioned, and where no coagulum of blood is mixed with the matter to account for the circumstance. I remember an instance of a boy who came into the hospital with an inflammation over the ascending colon. He said he had had a complaint in his bowels (as he expressed it) some weeks before, and that this inflammation came on subsequently. After he had been in the hospital a few days, there was a manifest fluctuation—it was clear that matter had formed, and accordingly I let it out. The abscess contained about six or eight ounces of white and apparently well formed pus, and it had the fœtid character that I have just mentioned. This was an instance in which the matter had formed near to a portion of the large intestine. I remember an instance of an Irishman, who came to this hospital with a swelling about the middle of the inside of the thigh, which was exceedingly painful, and in which no fluid could be found by examination. A poultice was applied, and other means taken to remove the pain, which was as-

cribed to the inflammation of the part. In a little time it became obvious that there was matter formed, and I evacuated it by a puncture: about two or three ounces of fœtid pus flowed out, mixed with coagulated blood. I also remember an instance of a patient who died in the hospital, in consequence of the inflammation of a vein consequent on venesection. An abscess took place in the upper-arm, which was opened before the patient died, and two or three ounces of matter evacuated, which was excessively fœtid.

You will observe that both the local and general symptoms in cases of abscess, the contents of which present the characters I have mentioned, are very severe. There is high local inflammation, and there is a corresponding degree of general febrile disturbance of the system; but when you come to open these abscesses, you find that the subsequent process is as favourable, and the recovery of the patient is as rapid, as if the pus had not presented the particular character that I have now stated. In short, there is nothing at all unfavourable in this state of decomposition of the matter.

I come next to speak of *chronic suppuration* or *chronic abscess*.

Respecting suppuration, I may repeat the same remark that I had occasion to make on the subject of inflammation—namely, that there are not exactly two degrees of it and no more; we cannot say there is just one degree which is acute, and one degree which is chronic. On the contrary, there are numerous degrees. On one hand you have inflammation in which the matter forms in a few hours, and which will come to the surface and be discharged in two days; on the other hand you have instances in which the formation of matter may take a long time, and in which it may remain for weeks and months without coming to the surface; and between these you have every possible gradation. The local inflammation that precedes the formation of pus in a chronic abscess is so slight, that it escapes observation, and you only become sensible of it when the tumor that is formed by the collection of matter is obvious to the sight.

I remember a medical practitioner bringing to me a youth who was apprenticed to him, and saying, "I wish you would look at a swelling in the thigh." I examined the part, and to my astonishment I found a large abscess. I enquired of my friend how long the youth had been ill, to which he replied he did not know, but he had only complained the day before. I laid open the abscess, and it contained more than a pint of matter. This youth, though in the medical profession, had been following his avocations, and had not mentioned that he had any thing the matter with him.

Some time ago a gentleman consulted me

relative to a tumor in the neck, and said that it had existed there about two years. He was a man of good constitution, and said that it had formed without pain; that he had observed it about the period I have stated, but it had not given him any uneasiness. On examining it, I decided upon making an opening, and found that it contained pus. Thus a chronic abscess had existed there two years, and contained about three ounces of matter, without having produced any active symptom.

In consequence of these collections of matter taking place in so insensible a manner, and being produced by inflammation of so slight a kind, we are liable occasionally to mistake them for tumors of a solid kind; particularly if the cyst which contains the matter should happen to be thick and firm in its texture.—Some time ago a female was shewn to me in consequence of a tumor in the axilla. She had a lump about the size of a moderate apple, firm, hard, and very deeply embedded in the axilla. She was about forty years of age. I examined it, and took it to be a solid tumor. I saw it again at some distance of time, and it appeared to be nearly in the same state. She said that it had never given her any kind of pain. On examining the circumstances connected with its formation, I could not trace any symptom to induce me to think it was not a tumor. I thought it necessary that it should be removed, deeming it to be a sarcomatous growth, and I appointed a distant day for performing the operation. Before putting the patient on the table, I again examined it attentively, and thought that I perceived fluctuation; and hence I was led to take the precaution of puncturing the tumor before commencing the dissection. When I made the puncture, out came a tea-cupful of well-formed matter.

I have seen an instance in the hospital, where a patient has been put on the operating table to have a tumor removed, when perhaps the idea has arisen, on examination, that it contained fluid: thus a preliminary puncture has been made, and matter has been evacuated. I recollect an instance of a patient coming from Wales, who had got a large tumor in her neck. I found it very solid, and no symptom of fluctuation; in fact, I dissected it out, and it was a very painful operation. When the tumor was dissected out, it looked uniform on the surface, and without any particular character. On cutting into it, it was found to consist of a dense cyst, filled with matter.

These cases shew you that matter may occasionally form with very little previous inflammation; and they afford you an important caution in any doubtful case, where you might entertain the idea of its being a tumor, to make a preliminary puncture. This is a safe measure, and which may save the patient the pain and suffering of a severe operation.

Such cases shew you that, in certain cases, although the formation of matter takes place in this insensible way, there may be so much consolidation of the surrounding cellular tissue, as to give rise to the production of a very dense, firm cyst; although generally in chronic inflammation the cyst is thin. In most of the cases that I have mentioned, and in the case of the gentleman in whom the abscess had formed two years, the cyst that contained the matter was so thin that you could not have told that there had been one at all.

In consequence, then, of chronic abscess forming with so little vascular disturbance of the part, and without any of the redness or heat which precedes suppuration in acute inflammation, and also in consequence of their taking place in a limb possessing apparently a natural temperature, they have been called *cold abscesses*, in contra-distinction to the abscesses resulting from acute inflammation, which are called *hot abscesses*.

There is another distinction between the two kinds of abscess, which is in the nature of the fluid they contain.

You will naturally expect that local occurrences, so dissimilar in their character, will produce very dissimilar results. You find, accordingly, that the matter of a chronic abscess is thin, approaching even to what we call a serous character; it is whey-like in its colour and consistency, and contains curdy matter in flakes. These flakes of matter which are contained in a chronic abscess, are sometimes discharged like portions of lymph, the word being often employed in a vague and indefinite way. But sometimes there are large fibrous masses met with in chronic abscesses—that is, masses of a hard or pretty firm fibrous texture. I do not know how to explain these occurrences. They are often large in size, and consistent in their composition, as if they were masses of cellular membrane. The fluid is frequently almost like serum; and it is from these circumstances that the name of *lymphatic abscess* is given to them: that is the term frequently employed by the old and continental writers. The inflammation required for the formation of chronic abscess is much less marked than that which produces the acute, and, as I have said, you will find, in general, that the cyst is much thinner; so that, when you come to examine the circumference of an abscess in the limb, it feels soft, and you might almost suppose that a fluid was contained in the natural texture of the part without being enveloped by a cyst: you do not find that it is walled in, and barricaded by the induration which characterizes the walls or sides of the phlegmonous abscess. For this reason, chronic abscess very easily extends in all directions in its circumference, and is apt to acquire a considerable magnitude, not having any

firm cyst to limit its extent—while it has no disposition to come to the surface. Thus it extends in circumference; and when the advance of the matter is opposed by fascia, as in the thigh, it may pass along the whole length of the limb without being disposed to point: in this way it may extend from the trochanter down to the knee.

Chronic abscesses generally belong to the head of what is called *spontaneous inflammation*—that is, they take place from *internal* causes, which, in most instances, elude our observation. Sometimes, however, they arise from obvious *local* causes. The irritation of a diseased bone, or joint, will produce a collection of matter of this kind. It is a collection of matter of this description, arising from such causes, that is termed *lumbar abscess*; where, in consequence of disease of the vertebræ, in the lower part of the back and loins, matter forms around the diseased part, and then descends, in the loose cellular membrane that covers the lumbar muscles along the side of the pelvis, into the thigh; or it takes its course along the back, and makes its way in different directions within and without the pelvis. Here you observe the feeble barrier which the slight cyst affords to the matter; for pus, which is formed high in the loins, will come down by its weight to the groin, or bore along the thigh nearly to the knee. Hence arises the distinction which is made between abscess of a part and abscess in a part: for the matter that has thus descended from the loins by gravitation into the thigh, can hardly be called abscess of this part.

This disposition to increase, in chronic abscesses, and this want of tendency to come to the surface, renders it necessary that we should discharge their contents by surgical operation. There is hardly any limit to the size these collections may attain, if you do not open them; but there is a difficulty in respect to the measure of evacuating them. When you open a collection of this kind, or when a spontaneous aperture takes place in it, if you proceed as you would in opening a phlegmonous abscess—that is, make an aperture so as to let the matter out, and then cover it with a poultice—the entrance of the air into the interior of the abscess produces decomposition of the matter it contains: this then becomes foetid; the surface of the abscess inflames; the secretion from its sides is altered; it becomes thin and stinking, and excessively irritating to the parts with which it is in contact. The inflamed surface of an extensive abscess thus excited, serious sympathetic disturbance in other parts of the economy occurs—in the alimentary canal, for example, and in the vascular system; and thus arises fever of a peculiar kind. This constitutional disturbance reacts on the local mischief, and the aggravation of the local disease again makes the

constitutional disturbance worse, and thus, between them, the patient is very frequently destroyed.

And here you must consider what I should have mentioned just now, when speaking of the causes of these abscesses. The remote or pre-disposing cause is almost invariably an unhealthy state of constitution. You find these abscesses occurring, not in healthy individuals, but in those whose constitution is naturally feeble; more especially in such as exhibit what is called technically a *scrofulous* disposition. You have to contend therefore, in these cases, both against the local mischief and against the bad state of constitution in which this local mischief has its principal origin. It is very desirable, then, to get rid of the contents of an abscess of this kind without incurring the risk of the evils that I have just alluded to. The particular mode of proceeding adopted by Mr. Abernethy, was designed to avoid this risk; and, in point of fact, you will find that, by proceeding in the way he has described, you may puncture the abscess, and get rid of the contents, without incurring the danger of inflammation of the cyst, or the constitutional effects to which it gives rise. His mode of proceeding consisted of making a small aperture into the abscess, allowing the contents to escape gently, and without suffering any introduction of air into the cyst; then closing the opening by adhesive plaisters, and thus putting it in a situation to be united by adhesion. In order to employ this mode with greater skill, he has stated that the skin should be drawn aside, so that when you let the skin go, the opening in the cyst and the skin should not correspond—that is, you make the opening valvular. After the abscess has been opened in this way, the matter will form again, and the necessity for repeating the puncture will arise several times. Under favorable circumstances the abscess will become limited in size, in consequence of these punctures. Its parietes contract when the quantity of its contents is diminished; and thus you bring it to so moderate a size that you make an opening in the usual way, and trust to the cure in the same manner that phlegmonous abscess would be healed. Such is the process when it goes on favourably. Of course you cannot expect such effects to be always produced in lumbar abscess. This mode of treatment is calculated to obviate the inconvenience that arises from exposing the abscess to the air; but the disease seated in the vertebræ, or adjoining parts, are sources of danger that require to be obviated by other means.

In conjunction with the means that you adopt locally in the treatment of chronic abscesses, you may at once resort to those which are favourable to the re-establishment of the

general health, and the improvement of the constitution. You would give the patient the benefit of a residence in pure air; you would attend carefully to the diet, seeing that it was light and nutritious; you would pay attention to the stomach and bowels, and to all the circumstances that contribute to promote health.

When the matter of a chronic abscess has been let out, in consequence of the cyst having but little disposition to take on the actions which would tend to obliterate its cavity, it is sometimes advantageous (if the nature of a part in which the abscess is seated will allow of it) to subject the part to pressure, and thus to promote a disposition to contract. Where a chronic abscess is seated in one of the limbs, a bandage may be applied over the part from which the matter has been so evacuated. Still an abscess of this kind very frequently remains in a state of fistula, and often the fistula is very considerable. Under such circumstances we occasionally succeed in accomplishing the cure by introducing a seton through the tract of the fistula. The presence of the seton excites active inflammation in the sides of the cavity: after this is produced, the seton may be withdrawn; and by pressure applied to the sides, they will frequently adhere together. Sometimes irritating fluids are introduced into the cyst, such as a solution of sulphate of zinc; but you must be cautious of doing this, and not think of irritating the sides of a cavity of this description where it is considerable: it can only be safely applied where the sides are of limited extent; or, failing this, it is necessary to keep up an opening till the parts heal from the bottom, and this is a mode especially adopted in those cavities which take place after the bursting of a phlegmonous abscess.

The constitutional disturbance which takes place when inflammation arises in the cyst of a chronic abscess, and when a copious suppuration occurs, is of that nature which is called *Hectic fever*.*

Hectic fever is a constitutional disturbance arising in a system weakened by long continued and serious local disease; more especially when such local disease is attended with suppuration. Hence it has sometimes been called *suppurative fever*. But the name seems to be objectionable, because suppuration very commonly occurs without any thing like hectic fever; and, on the other hand,

hectic fever may take place where there is no suppuration.

Hectic fever occurs in various *medical* as well as *surgical* cases. In extensive disease of the lungs you may have fever of a hectic character, without its having proceeded to suppuration; and you may have all the phenomena of hectic from affections of the large joints, where suppuration has not taken place. In various serious injuries, such as a bad compound fracture, it will generally happen that violent inflammation will take place in the limb; and, in conjunction with the serious local disturbance produced in that way, there is a corresponding inflammatory fever. Matter forms in consequence of the inflammation, which then generally becomes lessened. Subsequently inflammation will sometimes recur, and a fresh formation of matter take place; and fresh febrile attacks accompany it. In this way the strength of the patient becomes considerably reduced, and, after a length of time, the state of disturbance in the part becomes altered; the limb is not only swollen and red, and the seat of successive phlegmonous abscesses, but it is perhaps œdematous. Instead of having a firm tumefaction surrounding the abscess, and instead of having a formation of healthy pus, the parts will become flabby, and perhaps a discharge of thin matter takes place. With this change in the local symptoms, there is a corresponding alteration in the general system. The local disease has from an acute taken on a chronic character; and a similar alteration occurs in the febrile symptoms. The patient now has hectic—that is, a kind of chronic fever. In hectic fever, whether it arise in consequence of the change in the state of the local symptoms proceeding from severe injury, or whether it be connected with the irritation arising in the cyst of the abscess, or whether it depend on a disease in some important organ of the body, such as the lungs or joints, we find there is a considerable disturbance of the circulation. The pulse is accelerated, so that probably it rises from 100 to 120 and upwards; and it often remains for weeks, or even months, at 120, without sinking beneath this. The patient sometimes feels heated, and at others chilled; the surface of the body is sometimes red and flushed, and at other times pallid and cold; and frequently it is bathed in profuse perspiration. Slight degrees of exertion are sufficient to bring on flushing, which ends in perspiration. The tongue is moist, and perhaps clean. The functions of the digestive organs are frequently disturbed; and towards the latter part of the affection diarrhoea comes on, and can hardly be restrained. The perspirations that take place in the latter stages are profuse; as is likewise the discharge from the bowels. Hence this is called *colliquative sweat* and *colliquative diar-*

* The following observations on Hectic fever were made by Mr. Lawrence at the commencement of the Lecture which is to follow the present; but as their omission was accidental, and as the Lecturer stated "that they should have come before what he had to offer on Mortification," and requested that they might "be put in their proper place," we have thought it right to do so accordingly—reserving the subject of Mortification, to which Mr. Lawrence had proceeded, for the next lecture.—E. G.

firm cyst to limit its extent—while it has no disposition to come to the surface. Thus it extends in circumference; and when the advance of the matter is opposed by fascia, as in the thigh, it may pass along the whole length of the limb without being disposed to point: in this way it may extend from the trochanter down to the knee.

Chronic abscesses generally belong to the head of what is called *spontaneous inflammation*—that is, they take place from *internal* causes, which, in most instances, elude our observation. Sometimes, however, they arise from obvious *local* causes. The irritation of a diseased bone, or joint, will produce a collection of matter of this kind. It is a collection of matter of this description, arising from such causes, that is termed *lumbar abscess*; where, in consequence of disease of the vertebræ, in the lower part of the back and loins, matter forms around the diseased part, and then descends, in the loose cellular membrane that covers the lumbar muscles along the side of the pelvis, into the thigh; or it takes its course along the back, and makes its way in different directions within and without the pelvis. Here you observe the feeble barrier which the slight cyst affords to the matter; for pus, which is formed high in the loins, will come down by its weight to the groin, or bore along the thigh nearly to the knee. Hence arises the distinction which is made between abscess of a part and abscess in a part: for the matter that has thus descended from the loins by gravitation into the thigh, can hardly be called abscess of this part.

This disposition to increase, in chronic abscesses, and this want of tendency to come to the surface, renders it necessary that we should discharge their contents by surgical operation. There is hardly any limit to the size these collections may attain, if you do not open them; but there is a difficulty in respect to the measure of evacuating them. When you open a collection of this kind, or when a spontaneous aperture takes place in it, if you proceed as you would in opening a phlegmonous abscess—that is, make an aperture so as to let the matter out, and then cover it with a poultice—the entrance of the air into the interior of the abscess produces decomposition of the matter it contains: this then becomes foetid; the surface of the abscess inflames; the secretion from its sides is altered; it becomes thin and stinking, and excessively irritating to the parts with which it is in contact. The inflamed surface of an extensive abscess thus excited, serious sympathetic disturbance in other parts of the economy occurs—in the alimentary canal, for example, and in the vascular system; and thus arises fever of a peculiar kind. This constitutional disturbance reacts on the local mischief, and the aggravation of the local disease again makes the

constitutional disturbance worse, and thus, between them, the patient is very frequently destroyed.

And here you must consider what I should have mentioned just now, when speaking of the causes of these abscesses. The remote or pre-disposing cause is almost invariably an unhealthy state of constitution. You find these abscesses occurring, not in healthy individuals, but in those whose constitution is naturally feeble; more especially in such as exhibit what is called technically a *scrofulous* disposition. You have to contend therefore, in these cases, both against the local mischief and against the bad state of constitution in which this local mischief has its principal origin. It is very desirable, then, to get rid of the contents of an abscess of this kind without incurring the risk of the evils that I have just alluded to. The particular mode of proceeding adopted by Mr. Abernethy, was designed to avoid this risk; and, in point of fact, you will find that, by proceeding in the way he has described, you may puncture the abscess, and get rid of the contents, without incurring the danger of inflammation of the cyst, or the constitutional effects to which it gives rise. His mode of proceeding consisted of making a small aperture into the abscess, allowing the contents to escape gently, and without suffering any introduction of air into the cyst; then closing the opening by adhesive plaisters, and thus putting it in a situation to be united by adhesion. In order to employ this mode with greater skill, he has stated that the skin should be drawn aside, so that when you let the skin go, the opening in the cyst and the skin should not correspond—that is, you make the opening valvular. After the abscess has been opened in this way, the matter will form again, and the necessity for repeating the puncture will arise several times. Under favorable circumstances the abscess will become limited in size, in consequence of these punctures. Its parietes contract when the quantity of its contents is diminished; and thus you bring it to so moderate a size that you make an opening in the usual way, and trust to the cure in the same manner that phlegmonous abscess would be healed. Such is the process when it goes on favourably. Of course you cannot expect such effects to be always produced in lumbar abscess. This mode of treatment is calculated to obviate the inconvenience that arises from exposing the abscess to the air; but the disease seated in the vertebræ, or adjoining parts, are sources of danger that require to be obviated by other means.

In conjunction with the means that you adopt locally in the treatment of chronic abscesses, you may at once resort to those which are favourable to the re-establishment of the

general health, and the improvement of the constitution. You would give the patient the benefit of a residence in pure air; you would attend carefully to the diet, seeing that it was light and nutritious; you would pay attention to the stomach and bowels, and to all the circumstances that contribute to promote health.

When the matter of a chronic abscess has been let out, in consequence of the cyst having but little disposition to take on the actions which would tend to obliterate its cavity, it is sometimes advantageous (if the nature of a part in which the abscess is seated will allow of it) to subject the part to pressure, and thus to promote a disposition to contract. Where a chronic abscess is seated in one of the limbs, a bandage may be applied over the part from which the matter has been so evacuated. Still an abscess of this kind very frequently remains in a state of fistula, and often the fistula is very considerable. Under such circumstances we occasionally succeed in accomplishing the cure by introducing a seton through the tract of the fistula. The presence of the seton excites active inflammation in the sides of the cavity: after this is produced, the seton may be withdrawn; and by pressure applied to the sides, they will frequently adhere together. Sometimes irritating fluids are introduced into the cyst, such as a solution of sulphate of zinc; but you must be cautious of doing this, and not think of irritating the sides of a cavity of this description where it is considerable: it can only be safely applied where the sides are of limited extent; or, failing this, it is necessary to keep up an opening till the parts heal from the bottom, and this is a mode especially adopted in those cavities which take place after the bursting of a phlegmonous abscess.

The constitutional disturbance which takes place when inflammation arises in the cyst of a chronic abscess, and when a copious suppuration occurs, is of that nature which is called *Hectic fever**.

Hectic fever is a constitutional disturbance arising in a system weakened by long continued and serious local disease; more especially when such local disease is attended with suppuration. Hence it has sometimes been called *suppurative fever*. But the name seems to be objectionable, because suppuration very commonly occurs without any thing like hectic fever; and, on the other hand,

hectic fever may take place where there is no suppuration.

Hectic fever occurs in various *medical* as well as *surgical* cases. In extensive disease of the lungs you may have fever of a hectic character, without its having proceeded to suppuration; and you may have all the phenomena of hectic from affections of the large joints, where suppuration has not taken place. In various serious injuries, such as a bad compound fracture, it will generally happen that violent inflammation will take place in the limb; and, in conjunction with the serious local disturbance produced in that way, there is a corresponding inflammatory fever. Matter forms in consequence of the inflammation, which then generally becomes lessened. Subsequently inflammation will sometimes recur, and a fresh formation of matter take place; and fresh febrile attacks accompany it. In this way the strength of the patient becomes considerably reduced, and, after a length of time, the state of disturbance in the part becomes altered; the limb is not only swollen and red, and the seat of successive phlegmonous abscesses, but it is perhaps œdematous. Instead of having a firm tumefaction surrounding the abscess, and instead of having a formation of healthy pus, the parts will become flabby, and perhaps a discharge of thin matter takes place. With this change in the local symptoms, there is a corresponding alteration in the general system. The local disease has from an acute taken on a chronic character; and a similar alteration occurs in the febrile symptoms. The patient now has hectic—that is, a kind of chronic fever. In hectic fever, whether it arise in consequence of the change in the state of the local symptoms proceeding from severe injury, or whether it be connected with the irritation arising in the cyst of the abscess, or whether it depend on a disease in some important organ of the body, such as the lungs or joints, we find there is a considerable disturbance of the circulation. The pulse is accelerated, so that probably it rises from 100 to 120 and upwards; and it often remains for weeks, or even months, at 120, without sinking beneath this. The patient sometimes feels heated, and at others chilled; the surface of the body is sometimes red and flushed, and at other times pallid and cold; and frequently it is bathed in profuse perspiration. Slight degrees of exertion are sufficient to bring on flushing, which ends in perspiration. The tongue is moist, and perhaps clean. The functions of the digestive organs are frequently disturbed; and towards the latter part of the affection diarrhoea comes on, and can hardly be restrained. The perspirations that take place in the latter stages are profuse; as is likewise the discharge from the bowels. Hence this is called *colliquative sweat* and *colliquative diar-*

* The following observations on Hectic fever were made by Mr. Lawrence at the commencement of the Lecture which is to follow the present; but as their omission was accidental, and as the Lecturer stated "that they should have come before what he had to offer on Mortification," and requested that they might "be put in their proper place," we have thought it right to do so accordingly—reserving the subject of Mortification, to which Mr. Lawrence had proceeded, for the next lecture.—E. G.

rhœa—which term merely means melting; the substance of the body, as it were, melting away under the profuse discharge that takes place. The patient is generally restless and uncomfortable at night. The symptoms in hectic do not remain stationary through the 24 hours; on the contrary, there is, more particularly towards the morning, a visible remission of the paroxysms. Towards evening the pulse becomes accelerated, the body heated, and the patient feels restless and uncomfortable. In the course of the night he probably becomes bathed in a profuse perspiration, from the disturbance of the circulation terminating in that way. In the morning he is comparatively free from fever, and remains so through the day. Such are the principal features of that state which constitutes *hectic fever*.

It has been made a question, whether hectic fever can be cured. The question is, whether you can cure the disease that causes these symptoms; whether you can remove the local excitement which produces the general disturbance that I have now spoken of. If you can do this, you can cure hectic fever. But, in most instances, the local disease is of a very serious kind, frequently uncontrollable, and if you cannot put a stop to that, neither can you put a stop to the constitutional symptoms which it excites. You cannot expect that hectic fever can be cured while the causes that have given rise to it remain in full force. But in cases where the cause is such as to admit of removal, as, for example, in a severe disease of the joint of the knee, which may be removed by amputation, you will find that all the worst symptoms of hectic will speedily cease when the source of irritation is gone; you will find that the patient then obtains rest, his appetite returns, and, in fact, his strength is speedily recovered.

What, then, is the treatment that is suitable to hectic? If you regarded merely the state of the vascular excitement, you might suppose that it would be necessary to adopt some means that might directly diminish that excitement, but you must take into view at the same time the condition of the patient in other respects. No powerful means—no direct kind of depletion, would be borne; they would merely lessen the powers of the system without doing good. Your object, in fact, is to sustain the strength of the patient—to keep up the powers by means that do not at the same time excite. You would then be inclined to give the lighter kind of tonic medicines—the dilute mineral acids, with light bitters, such as bark and cascarrilla. You would let the patient take, in small quantities, light, but nutritious diet. The dilute muriatic, and the dilute sulphuric acids, possess as much power as any means you can employ in checking the profuse perspirations which are often so troublesome in

hectic. When a patient is unable to obtain rest—when he passes uncomfortable nights, you may occasionally see it necessary to administer narcotics. It is on the whole a kind of temporizing plan, in which you endeavour to administer mild remedies to support the strength, without adding to the excitement.

ON THE TREATMENT OF ASPHYXIA FROM DROWNING, &c.

HAVING frequently experienced considerable embarrassment in my endeavours to establish the resuscitative process in cases of asphyxia from drowning, intoxication, &c. I have been led to consider how that process may be best simplified, so as to be performed with the least possible delay, where even the apparatus of the Royal Humane Society is not to be procured.

It is much to be deplored that there are not regularly-established receiving stations, as near as possible to every place of danger, and at all times *amply furnished* with the means of applying artificial heat *simultaneously*, with every other requisite for the successful inflation of the lungs, &c. For want of such accommodation, I verily believe that in nine cases out of ten either these means are not attempted, or the attempt is so inefficiently made as to afford not the smallest chance for the recovery of the individual; while the operator is placed in circumstances of the greatest possible embarrassment. Let the reader imagine an unfortunate individual taken out of the water, perhaps after only five or ten minutes submersion, and after some delay conveyed to a public-house. Some publicans refuse to receive them; and those who do (at least many of them), afford not the smallest convenience or accommodation, from an idea that there is no one to indemnify them for the trouble and expense likely to be incurred*. Under these circumstances,

* As the following excellent rule of the Society cannot be too generally known, I take the liberty of inserting it.

"Rule 6.—That remuneration† be given to any publican, or other person, who shall admit the body of any object into his house without delay, and furnish the necessary accommodations, and that they may be secured from the charge of burial in unsuccessful cases."

† "One guinea is always paid to a publican who readily takes a body into his house, with the hope of recovery."—*Annual Report*, 1829, p. 71.

a medical man is called to pronounce on the life or death of the individual, or to employ the means recommended by the Royal Humane Society, in a place wherein he has no authority or command, surrounded by a crowd of useless idlers (men, women, and boys), in the tap-room of a public-house. Perhaps, by way of appearing to do something, a vein is opened (a practice, however, very seldom proper), or he makes an attempt to inflate the lungs, with such means as are in his power, and finds the mouth, nose, fauces, and trachea, occupied by frothy mucus, water, and the *contents of the stomach*; not a rag nor a blanket is to be had, and he is reluctantly obliged to abandon the sufferer to his fate. I would gladly prevent the repetition of such an unfortunate result, in every case wherein the circumstances seem to promise the most distant hope of recovery.

I have always considered it to be of primary importance to obtain, as quickly as possible, a source of artificial heat; and the difficulty of doing this, in general, is the principal cause of failure; for though the restoration of respiration will bring with it the restoration of animal heat, yet before this can be effected, the body, in most cases, becomes too cold for artificial inflation alone to restore its temperature. It is important to husband the small remnant of vital warmth, by preventing evaporation from the surface, either by drying the body and covering it with warm blankets as speedily as possible, or by immersing it in a warm-bath. In general the body is exposed naked too long, or the wet clothing is suffered to remain about it, from the ignorance or apathy of the by-standers, &c. Frictions of any kind are of no avail until the skin has regained, with its warmth, its susceptibility to stimulation, and are, moreover, rather an impediment; as the body is almost necessarily too much exposed, and time is misemployed; or lost.

The remedy for this great impediment to the successful performance of the resuscitative process, is not within the power of individuals in the situations wherein these accidents are of most frequent occurrence; and it is a subject worthy the consideration of the heads of the new police, or of the parochial authorities in every place, whether it be not possible, as well as highly

desirable, to appropriate some small building, or room, additional to the watch-house, or other more convenient spot, to this especial purpose. I think it would not be difficult to contrive, with great economy, a kind of artificial hot well, which should at all times be ready for use, and would only require to be visited once in twenty-four hours, or even less frequently, to see that it is in order. I would propose a room about twelve feet square, to be furnished with the means of procuring and keeping ready oxygen and hydrogen gases; the former for inflating the lungs, the latter to keep a body of water constantly at the temperature of 98° Fahrenheit at least, with power of increasing it at pleasure at a minute's notice. Indeed they might be built on a smaller scale, and every light-house, harbour, or convenient station along the sea-coast, and in the course of rivers, &c. might be thus provided in the manner of Martello towers; or even on board ships a place might be set apart for these purposes.

It is very seldom, indeed, that the practitioner has it in his power to avail himself of the important agency of the Galvanic fluid; neither could a single person, with the ordinary apparatus, attend to this, while all his attention is engrossed by the endeavour to restore respiration. But this may be obviated, in some degree at least, if not very efficiently indeed, by lining the bottom of the bath with woven copper wire-work, in the manner of a bed-sacking. The body being laid upon this, and the water let in, should then be covered with a similar piece of work, but flexible in the manner of mail, of zinc wire; by which means a simple galvanic circle would be formed between the two metals and the water, and a current of this energetic fluid would pass from the one metal to the other through the whole body, the respiratory process being *uninterruptedly* carried on at the same time.

In addition to which I have devised, for the same purpose, a very simple, and, as I hope, valuable instrument, capable of being instantly and efficiently employed in all places, even where the former means cannot be obtained. I have before observed, that the ordinary attempts at inflating the lungs are often defeated by the contents of the stomach occupying the mouth, nose, and

fauces, choking the instrument, and perhaps getting into the trachea itself, on the first attempt to expel the air from the lungs by pressure upon the abdomen.

In order, then, to carry on the inflation of the lungs *without interruption*, and to stimulate the stomach at the same time, I propose a silver tube to be passed into the stomach, and retained there; its lower orifice should be large, so as to admit the solid as well as the fluid contents of the stomach to enter it. The stomach-pump is then to be attached, and the stomach emptied as speedily as possible. A cordial may then be injected through the tube, which is not to be withdrawn. To its upper extremity may now be attached the remaining portion of the instrument, which consists of a flat piece of zinc, bent to the curvature of the neck and chest, intended to lie flat on them, and to terminate at the scrobiculus cordis, in an expanded plate of the same metal. The upper part of this piece of zinc to be furnished with two handles, crossed in the manner of a pair of forceps, one of zinc, the other of silver; which is made to be easily attached to the œsophagus tube, as a bayonet is locked upon a musket barrel. The whole instrument thus forms a large pair of forceps of a rather singular aspect. On gently compressing the handles (which should be of glass, or any non-conducting substance), the blades will be approximated as near as is desirable, and all the important organs included between them be subjected to the stimulus of a simple galvanic circle, thus formed between them and the two metals.

And now let the anatomical reader reflect on the number and importance of the vital organs included in this circle of action. Besides the œsophagus and trachea, the heart and lungs, the diaphragm and its nerves, the stomach and its nerves, branches from the hepatic plexus, and other portions of the great sympathetic apparatus. The position of the body all this time is semi-recumbent, sitting or reclining in the bath, with the head and shoulders elevated, and placed in such a position as will bring the mouth, œsophagus, and stomach, as nearly as possible into a straight line. Some unusual difficulty may be anticipated in passing a rigid tube into the stomach, but when the passive state of the body is recollected,

and the usual directions for passing the œsophagus bougie are observed, viz. to keep the instrument against the back part of the pharynx, and the mouth in a line as near as possible with the cardiac orifice of the stomach, the most inexperienced person, acquainted with the anatomy of the parts, will scarcely be disappointed. But as it may be desirable that persons, not supposed to possess that knowledge, may be instructed in this particular, plain directions, with a description of the relative position of the parts concerned, and their separate office, should accompany the instrument.

The zinc portion of the apparatus is curved laterally to the left, so as to lie out of the way of the pomum Adami, for the following reasons:—The usual mode of inflation cannot be resorted to in conjunction with the means above described, as the mouth and nose are necessarily left free and open. But a more commodious method of inflation may be *simultaneously* carried on, in the following manner:—An opening is to be made into the larynx with the point of a lancet, just above the ewer-shaped lip of the thyroid cartilage; a small tube, formed with a shoulder, is to be introduced, and an elastic gum gas-holder, furnished with a stopcock, and filled with oxygen gas, is to be attached. On the opposite side also a similar one may be attached, distended with atmospheric air, so as to dilute the pure oxygen to any required degree, regulated by the turning of the cocks: a change of these vessels will be required to be kept up, and where oxygen gas cannot be obtained, they may both be kept filled with atmospheric air, by means of a common air syringe, and thus form, by their gentle and equable action, a method of inflation more nearly resembling natural respiration than the bellows are capable of, and which may thus be superseded altogether. This mode of laryngotomy is no new operation. It has been constantly and strenuously recommended by my worthy and respected preceptor, Mr. Brookes, in his lectures, not only as a facile mode of access to the trachea, but as being free from all risk of dangerous hæmorrhage, to which the usual operation of tracheotomy is liable; and because of the vicinity of the chordæ vocales, or ligaments of the glottis, parts so very sensitive as to retain their

excitability much longer than others; So that on all accounts it is an operation that deserves to be extensively known, and more generally practised. It is very safe, and may be performed with confidence by a tyro in anatomy.

A doubt may arise in the minds of some persons whether the galvanic action may not be too powerful; but it is in some degree limited, by the necessary size and form of the œsophagus tube. The number of square inches of zinc can be very easily regulated. However, if it be found tolerable in the living or healthy body, of which I have little reason to doubt, it cannot be too strong under the circumstances of asphyxia. On the other hand, should it prove to be too weak, I think means may be found of greatly increasing the metallic surface, internal as well as external. The common electrical machine is quite inapplicable to these cases, because (independently of its expensiveness) of the utter impossibility of keeping it ready for immediate action under all the circumstances of time and place.

Recapitulation.

The body, if clothed, to be immediately stripped and immersed in the warm bath, or in its absence, to be dried and placed in a warm bed. The tube to be passed into the stomach as speedily as possible, and the contents to be withdrawn. It will often be found full of food; for a full stomach contributes to the facility of drowning, by increasing the specific gravity of the body. The galvanic action to be commenced at the same time, by attaching the blade or limb of zinc, the skin beneath which should be moistened with a warm sponge (where the bath is not used), or with a little liquor ammoniæ or culinary mustard, and a cordial of hot brandy and water, with a tea-spoonful of mustard, to be injected into the stomach.

Laryngotomy to be performed, and the lungs inflated in the manner herein recommended. This process to be continued until respiration is fully re-established. The heat of the bath to be gradually increased, and kept up to 120° of Fahrenheit. When the patient is considered to be sufficiently restored, the body is to be rubbed thoroughly dry, and placed in a warm bed. A gentle anodyne may then be administered, and half a pint of warm gruel, in

preference to tea or spirits. The patient should be carefully attended during sleep, and until healthy actions are completely re-established. I have found the tin bottle, called a stomach-warmer, of great utility; I therefore recommend this to be applied, and bottles of hot water laid at the feet, &c. when the patient is put to bed.

In conclusion, let me observe, that I have written this paper with the distant hope of drawing the attention of local authorities, and the public in general, to this, now rather neglected, department of practical medicine. That an apathy pretty generally prevails on this subject will, I think, be conceded to me. Perhaps it is to be attributed to the great increase of population of late years that the value of human life is depreciated, and from the same cause the profession of physic suffers a corresponding depression. But there is a singleness of purpose comprehended in the prevention and cure of disease, and the saving of human life, which should at all times actuate the professors of our art. I am aware how difficult in execution some of my plans will be found, unless they are seconded by influential persons in every part of the kingdom. Another great difficulty will be to interest medical gentlemen themselves sufficiently, to give up so much of their time and thoughts as the subject requires; for few men are called on to make greater sacrifices than they, and there are few that can afford to do so without any prospect of an adequate remuneration. As a means of meeting this difficulty, I will avail myself of a suggestion of my friend, Mr. M. Blood, who proposes that there should be a sprinkling of medical officers appointed to the superintendence of these and similar matters in the new police, who should take their rotation on duty, so that no case should by possibility escape their vigilance, or miss the opportunity of a prompt and vigorous application of the means therein recommended. It may reasonably be doubted whether medicine, or questions connected with it, are, at the present time, fit subjects for the consideration of the legislature, as this depends on the value, for the time being, of human life. That this is relatively smaller now, in a time of profound peace, with a superabundant population, than at any other period of our history, may be attributed also in a very

great degree to the advanced state of the science of medicine. But in proportion as the value of human life diminishes politically, so it becomes of greater importance individually, and behoves each of us to inquire into the resources whereon we are to depend in the event of dangerous accident or disease. Yet it is seldom that men can be induced to provide against a remote and contingent danger, while in the enjoyment of perfect health, and these are evils only felt when they come home to our own doors. And finally, I solicit the attention of the profession and the public, with deference, to these or similar measures, because the chief excellence of any good consists, not in its peculiar richness, rarity, or even in its abundance, but in its ubiquity, and that at the precise time when it is most required.

HENRY BOND.

P.S. The instrument may be had of Mr. Stodart.

OPENING OF THE MEDICAL SESSION IN DUBLIN.

*To the Editor of the London Medical
Gazette.*

SIR,

No good reason, I presume, can be assigned why the medical session commences so late here—a full month, and more, after the commencement of business in London. Old prescription, and university custom are, perhaps, the best that can be given. Medical education, however, can hardly be much longer confined within its present narrow limits: increased and multiplied as its objects have become, six months out of the twelve are quite insufficient for the purpose. Our medical reformers and modern economists of time, would do well to look to this. It is a fond notion to talk of the necessity of relaxing after the winter campaign—of laying in a stock of health during the summer months—that those months are unfit for dissection, &c.; all so many pleas for idleness. In the olden time, indeed, our sapient and grave forefathers took ample “time to play;” all they had to teach, could very well be taught in a few months; lectures were exhausted before the spring was expired, and the *long vacation* was a necessary consequence of having nothing to do. In the great

seats of learning the same strenuous idleness still prevails; but it is a bad precedent for our profession—the beaten track is no longer advisable, or safe. Why may not our professors exchange partridges for pupils on the first of September, and favour us with nine months’ courses? I leave the consideration of the project with their gravities.

An obvious consequence of this tardy opening of the session is, that the students are not steadily at work till after the holidays. What with the public lectures, and the bustle and arrangement of entering on business, December is come before their hands are rightly in. This is a serious loss of time, which is not sufficiently attended to.

A rumour was afloat here lately, that the terms were to be raised in all the schools this winter. I find it is not true: and yet, if both Dublin and Paris were to take advantage of the present state of things in Britain, it were not to be wondered at. It is all quite fair in trade, as the world well knows, to make the most of the market; those who command the supplies, may also command the price of the commodity; nor will the traffic in the dead be found to differ much from other kinds of traffic. Among the “uses of the dead to the living,” this has, I think, been rather overlooked; this curious feature in the history of modern times—the *profitable* trade so extensively driven in human flesh. Long ago, the mummy system was profitable. “Mizraim cured wounds, and Pharaoh was sold for balsams;” but these worthies were stale for our markets. We want the flesh, recent and succulent, almost as Shylock himself would have it; and such, it seems, we can have at any time for our money; thanks to the glorious condition of the statutes! Dublin has always been well supplied, and has been able to supply a neighbourly share to the sister kingdoms, and for a reasonable “condition;” little more than prime cost. But ought they to grumble if the markets rise ere long? Common sense would dictate the prudence of profiting by the occasion; and the circumstances of the late anatomical bill (exclusively for the benefit of Great Britain—poor Ireland being left to shift for herself!)

* Sir A. Cooper’s evidence before the Anatomical Committee is here referred to.

might provoke a reprisal. Yet she has taken no ungenerous advantage—"her commercial relations remain unaltered."

The public lectures are a prominent object in the opening of our session. In imitation of the university course, originally intended for the students in arts, but long since liberally thrown open to the public at large, a certain number of free lectures are annually given in each of the schools in Dublin. In this respect, perhaps, no city in the empire has more opportunities afforded its inhabitants for cultivating a general acquaintance with the various branches of natural science: the professors of anatomy, chemistry, botany, mineralogy, and mining, connected with our well-endowed establishments, devote every year a certain portion of their labours to the diffusion of useful knowledge among the people. But what costs little, is seldom estimated at much; and it is to be apprehended that the gratuitous offering of this instruction does not contribute much to the enhancement of its reputed worth. This may be one cause why, in so populous a city, so small a proportion of general auditors is to be observed in our medical theatres, even on occasions when the public are invited to attend; a circumstance the more remarkable, as so large a number of medical students (probably seven or eight hundred) assemble every winter in Dublin, and cannot but contribute to keep public interest alive with respect to the profession. The chief cause, however, I suspect, is to be traced to the professors themselves: with a very few exceptions, there is a lamentable lack of spirit among them; and of that spirit-stirring talent which is so necessary for drawing together and entertaining a popular assembly. They want the elements of usefulness which professional enthusiasm and native eloquence can alone supply; and I may add, that exuberance of general knowledge so indispensably requisite for the illustration of medical topics. They cannot, they will not break, the numbing spell that binds them; nor will they step beyond the magic circle of routine to which they have been so long habituated. By habit, converted into mere machines—a sort of barrel-organs—they throw off a stated number of soporific tunes, and there they stop, until again set a-going to pursue the same perpetual round. It is unplea-

sant to be obliged to pronounce so sweeping a sentence on the Irish professors; exceptions there are, undoubtedly—but only just so many as to establish the general truth of the position. At the present moment it would be criminal to suppress the fact, when it is universally understood how fair a field is thrown open to the active energies of men of talent. The materials are ready; the impulse of the master-mind alone is wanting, to quicken and rouse them into life. In a word, sufficient excitement is abroad; the desire of knowledge is abundantly manifested; society is prepared for improvement, but the sources are miserably dried up: and in ministering to this epidemic thirst, how admirable an opportunity is afforded the able and judicious teacher of medicine, to dispel the mists of ignorance and error; to beat down prejudices beneath his feet, and to raise up medicine to its rightful place on the pillar of popularity. Genius could not be applied to a nobler object. Taste, talent, learning, and eloquence, might all be enlisted in the cause; nor could they have a prouder arena for their display.

The late recurrence of the annual public courses naturally gives rise to these remarks. It is strange that any thinking person should be so shortsighted as not to be sensible of the good effects which these courses, well managed and directed, might be so ordered as to produce. There are ebbs and flows in public feeling, and the different branches of knowledge are subject to vicissitudes. The prevailing taste, at present, is decidedly for natural history. The general facts of zoology in particular, and comparative anatomy, seem to enjoy a remarkable currency in our educated circles. It amounts, indeed, I would almost say, to an influenza; in fact, it is *the rage*. Nor is it confined, it would seem, to this kingdom alone; the popular writers of Great Britain are sensible of the reigning predilection, and the press teems with innumerable productions in accordance with public feeling.

By a sort of coincidence, rather accidental, perhaps, than designed, the College of Surgeons here have directed their professors to deliver twelve lectures annually, on the subject of comparative anatomy, preliminary to the usual anatomical course; and however ridiculous it may seem, to enter upon

the study of anatomy by engaging at once in its most intricate and extensive consideration, and to pretend to convey even a smattering of it in twelve lectures, yet the measure is not undeserving of some credit. It has secured a certain portion of popularity already, and no doubt, in time, may prove useful, when it has received those improvements of which it is so susceptible. On the recent occasion, Dr. Jacob, the Professor who *opened* in the School of Surgery, aware, it is to be presumed, of the difficulties he had to encounter, contented himself with lecturing on the invertebrated animals of Cuvier; and he had, of course, more than enough to do, to dispatch even those three lowest classes of the general division. I must confess, however, that I feel strongly inclined to doubt the utility of the whole undertaking: it is extremely questionable whether any of his auditors, except those of a certain standing, were edified by his labours; the general auditors, unconnected with the profession, certainly were not. Perhaps, too, it were more wise of Dr. Jacob to have adopted some simpler classification than that of Cuvier; that is, supposing Dr. Jacob more willing to profit than to puzzle his auditory. The adoption of it naturally and necessarily occupied much time in defending its complicated refinements, and explaining its absurd nomenclature; the latter, the lecturer himself seems not yet sufficiently to have mastered. How much too of his introductory lecture might have been spared! Instead of the "very few words" with which he proposed to preface his subject, we were treated to a critical essay on the merits of Haller and of John Hunter. Then we had the Baconian text, that "knowledge is power," amply descanted on; and we were gratified with the information, that "a man who walks the streets in rags, if he have knowledge, has rank in society." Comfortable and encouraging assurance to the medical aspirant! I recollect, too, a curious, and to me, I confess, a *new and wonderful* piece of intelligence communicated at this lecture. Here were we for the first time taught, that the organic life of an individual might be extinct, while the animal life still remained; and that, too, in great perfection:—"For instance," says the professor, "in the last stage of phthisis, for some time be-

fore death, the heart has ceased to beat—absorption no longer goes on—digestion, respiration, and the other functions, are no more—yet the individual enjoys his intellectual faculties; he converses most rationally with his assembled friends," &c. This appears to me to be quite original; and I am anxious to secure to Dr. Jacob his right of property in it: certainly Bichat never dreamt of such a combination in his ingenious speculations on life and death.

To what will this love of paradox come at last? That any Munchausen tale may be safely started, and will be most assuredly gulped down by an admiring crowd, gaping for novelties, has now been fully proved. Let young professors profit by the knowledge of the fact; and if they do not succeed in satisfying their auditory, and in attaining high eminence as lecturers, why they have no romance in their heavy constitutions,—that's all.

With far more discretion, and infinitely better judgment, Dr. Macartney improved the opportunity which lay open to him. Sensible of the prevailing mania for zoological inquiry, and of the absurdity, and indeed the impossibility of attempting to enter on a system within the limited period, he chose rather to take up a part—a small, though a most important part of the general subject. The anatomy and physiology of the senses, illustrated from the stores of his accumulated knowledge, formed the subject of *his* course; and perhaps a tissue of more valuable matter was never laid before the public within the narrow compass of twelve lectures. After a masterly view of the nervous system and of the functions of the brain—in which the phrenologists were not forgotten, (by the way, Dr. Macartney has never been seduced by the plausibilities of these enthusiasts)—the five senses, in the order of feeling, taste, smell, hearing, and sight, were treated with singular ability. Nor let it be deemed a task of little difficulty to do this well; for it is the privilege of men of superior talents alone to form those comprehensive views which guide them in the diffusion of precise and useful information. The ease too, the fluency, and the aptness of expression in which they are conveyed, render Dr. Macartney's lecture popular that can be con- ever tire, their inter-

he should be heard repeatedly on the same topic, he is ever original—ever new. Anecdote, history, personal experience, and acute criticism, are brought to bear on every subject, however dry in other hands, and are poured out in boundless profusion, whilst with the grand object—utility, ever in view, he never confounds his unprofessional hearers with the verbiage of technicality. Opposed to all idle display on these tempting occasions, he merges his superior claims as a comparative anatomist, and author of the best articles on the subject in our language, and presents himself in his crowded theatre with the unaffected plainness and unembarrassed self-possession of a man of genius. His language is always appropriate, chiefly conversational, or in the form of interesting narrative. It is, however, occasionally elevated with his theme, and in the ardour of vindicating the dignity of his profession. With pride we heard him, at the close of his introductory lecture, in energetic terms, allude to the lustre conferred on moral science by medical men, and we felt the animation with which he referred to the labours of “Aristotle, a working anatomist—and John Locke, a practising physician.” Nor should we overlook his zeal in the promotion of his favourite design—the removal of that prejudice and error which so generally exist in society with regard to the practice of dissection. He has always some pithy argument wherewith to pose his babbling adversaries. I recollect upon one occasion lately, in the public course, he hinted at the propriety of our learned judges being made aware, that “much of the silly nonsense they deliver from the bench against the practice of anatomy, is uttered by means of dead men’s teeth; and the ladies too, who sometimes indulge in fantastical remarks on the same subject, ought to be reminded, that much of their beautiful hair and their white teeth, of which they are so proud, are, in truth, the property of the grave!”

I shall close this paper with a brief allusion to what took place at the College of Surgeons on the last day of the public course. According to the sentence of the law, and that obnoxious portion of it which would surely be “more honoured in the breach than in the observance,” the bodies of the murderers, Magrath and Mellon, were

conveyed from the gallows to the College of Surgeons for dissection. The usual galvanic experiments were performed on them by Dr. Apjohn, in presence of a thronged assembly; and Dr. Ure’s celebrated processes were attempted to be verified. Every circumstance seemed favourable for a fair trial—the bodies had not been suspended for a longer time than Clydesdale’s, nor were the cervical vertebræ dislocated. But the efforts to produce respiration, much more to restore life, were utterly vain. The common contractions were very well displayed, and the effects produced upon forming a circuit between the supraorbital nerve and the heel, were rather striking and remarkable. For all the good, however, that resulted from this experimental exhibition, it might as well have been let alone; and I will add, that a nobler use might have been made of these murderer’s bodies. Here was a fine opportunity afforded the professors of the school of surgery to display a disinterested regard for the credit of their art. By the sacrifice of a few paltry shillings (the perquisite of the pair of murderers was not worth more than thirty,) they might have proclaimed to the world that *dissection* was *no punishment*, and if it were, that they disdained the executioner’s office, or one still more odious than the hangman’s. They should have declined being “finishers of the law.” But, no doubt, the sweet savour of the prey was irresistible:—

As when a flock
Of ravenous fowl come flying, lured
With scent of living carcasses, designed
For death the following day, in execution:
So scented th’ anatomists, and upturned
Their nostrils wide into the murky air,
Sagacious of their quarry. MILTON.

Certainly, with the evidence of the most respectable members of their profession before their eyes—unanimous as to the folly and wickedness of countenancing the obnoxious clause in the murderers’ sentence—the anatomists of the school of surgery in Dublin clearly stand convicted of having acted an unworthy part. It was, to say the least of it, an ill-advised proceeding to accept those bodies for dissection.

Yours, &c.

EBLANENSIS.

Dublin, Nov. 24, 1829.

COLLEGE OF SURGEONS.

To the Editor of the London Medical Gazette.

SIR,

I HEARTILY congratulate yourself and the public upon the almost complete subversion of that mischievous publication called the *Lancet*, which has been effected through the means of your *Gazette*. But though, to speak technically, you have removed the predisposition on the part of the profession to be infected by that envenomed instrument; and whenever it has been insidiously employed in its former practice of slanderous inoculation, you have speedily supplied the antidote; yet, in my opinion, more is still required to be done. The *Lancet* has defamed many institutions and persons of well-merited respectability; and though such slander can produce no permanent effect, yet a tarnished character does not speedily acquire its former manifest perfection and brilliancy. The aspersions wear off by degrees, but whilst any stain remains the party is liable to suspicion. If, therefore, the respectability of a slandered institution be of importance to the public, such stains should be removed by a speedier process than that of the slowly moving hand of time.

The Editor of the *Lancet*, and his coadjutors, have strongly censured the conduct, and scurrilously misrepresented the motives of the Directors of the Royal College of Surgeons in London, so as to prejudice a considerable party of its members against that institution. Now, should an application be made to the legislature, for an alteration in any of the departments of the medical profession, which is an expected event, as the hostile feelings of the members are likely to influence public opinion, and thus produce results permanently injurious to our profession, it surely must be proper to submit to the medical public a narrative of the proceedings of the college, the correctness of which may be ascertained by any of its members.

The writer of the present article, though indifferent whether his name be known or not, does not wish to publish it on the present occasion*. If, then,

* We must, therefore, leave our readers to guess who the author is; we shall only say that he was one of the most eminent surgeons in London.—E. G.

Mr. Editor, for the sake of justice, and in expectation of doing good to the profession, you will insert my narrative and comments in your *Gazette*, you will much oblige

A PROFESSIONAL FRIEND.

It is not necessary to go back farther than the reception of the present charter, since it is the authority under which the censured acts of the college have taken place. When the college expended upwards of 30,000*l.* of its own money, in addition to the 27,500*l.* granted by parliament, to prepare for the reception and display of the Hunterian Museum, the downfall of the institution was solemnly and fearfully predicted by many of its elder members, who were men of intelligence. They, however, made their calculations on the *status quo*; they did not anticipate the great influx of persons into our profession, and the consequent influx of funds to the college. As soon as the finances of the college were retrieved, and it was deemed capable of supporting its necessary expenses, all contributions were taken off from its members, and the fee for its diploma was reduced.

In order to ascertain and promote the proper classical education of youths entering into the profession, the college offered advantages to those who were brought there to be articled, which afforded the Court of Examiners an opportunity of inquiring into their classical attainments. That such education should be continued as long as it could conveniently, the court refused to article youths as students till they were sixteen years of age, or to examine them as candidates for a diploma until they were twenty-two. Yet fault is found with this regulation. The surgeons of provincial hospitals say, that it offers equal facility of admission into our profession to those who serve the greater part of their apprenticeship in compounding medicines, as to others who are articled to hospital surgeons, and have passed their time in attending those institutions. Now before the late disturbances began, the college had agreed to admit four years' attendance on a provincial hospital by an articled student before the commencement of his regular anatomical and physiological studies, as equivalent to the half of the hospital attendance required from him when a candidate for a diploma.

Moreover, the hospital surgeons in a metropolis say, that their apprentices ought to be distinguished from others; that they attend anatomy and physiology, and have an extensive sphere of practical observation and information open to them from the very commencement of their articles; and, therefore, that a less time should be required from them to qualify themselves to take out their diploma. In either of these instances, it is manifest that interested motives influence the complainants, who do not seem to consider the difficulty of making regulations to suit variety of cases.

The strictness of the examination of candidates has also progressively increased with the improvements of science. The great number of candidates who have been referred by the court to a longer continuance of their studies, has induced students in general to look forward to their examination with considerable apprehension, and to prepare themselves for it by proportionate diligence. Persons who were members of other colleges have affirmed, that the examinations of the London college, though brief, were in their opinion a more effectual test of professional attainments, than those to which they had before submitted in other places.

It was formerly the practice of the Court of Examiners here, as it is in some other Colleges, to inquire into the professional attainments of candidates by committees of the examining members; but of late, each candidate has been examined separately, in the hearing of the whole court. Thus have the examiners voluntarily expended great additional time and attention, in order more perfectly to perform their important duty.

The Court of Examiners knew that many of the provincial hospitals of this country presented a larger field for the acquirement of practical knowledge than is to be met with in some of the metropolitan hospitals which it has recognized as schools of surgery; and often deliberated on the propriety of receiving certificates of attendance on such provincial hospitals, as testimonials of proper professional education. The court had hitherto been withheld from so doing, from knowing that, in order to profit by opportunities of acquiring practical information, a student must

previously possess a knowledge of the structure and functions of the various organs and parts of the body, of the nature of diseases, and of the principles upon which they ought to be treated. Yet, as soon as it was perceived, from the great influx of persons into our profession, that the recognized hospitals were likely to overflow with students, so as to impede the ready acquirement of practical knowledge, the court decided to admit certificates of attendance on provincial hospitals upon certain conditions.

The funds of the college have been at all times liberally expended in making great additions to its museum, and in keeping it in a state of unrivalled order and preservation. With respect to the library, it should be publicly known that the college, till of late years, did not possess one hundred volumes. The formation of a library for the use of the members, and to promote the scientific knowledge of our profession, was at the suggestion of the Directors of the College. The belief that the funds might be inadequate, induced Sir Charles Blicke, in 1816, to leave a legacy to the college, that the annual interest might be expended in the purchase of books. The same belief induced the Council at first to allot only small sums not exceeding 100*l.* per annum, to the gradual augmentation of the library; but it was proposed to vote a sufficient sum for its completion, so that it might be opened as a library of reference for the use of the members.

After a long series of well-intended conduct, the Directors of the college flattered themselves that they had deserved, and even obtained, some degree of public approbation, as a reward for a great and gratuitous devotion of time and labour in the service of the profession.

I proceed to relate the circumstances of that act of the college which gave rise to the late disturbances.

The Court of Examiners had always been accustomed to receive certificates of attendance on anatomical lectures, as credentials of the proper professional study of candidates, well knowing that such lectures included both physiology and pathology. It would have been in vain to have required students to attend separate lectures on physiology and on morbid structures; for such lectures have not been given separately in this

country. In consequence of the great increase of persons educated to our profession, many additional schools of anatomy were set up; in which students were by no means so amply instructed in the principles of professional knowledge, as in those which had been previously established. From the temporary necessity of instructing young men for the service of the army and navy, a summer course of anatomy was first given in this metropolis. Progressively, persons became teachers of anatomy, who had neither preparations nor drawings illustrative of the subject, and who merely taught common and coarse dissection, unassociated with either physiology or pathology. Certificates of attendance on anatomical lectures were presented to the Court of Examiners, signed by persons unknown to any of its members. Under these circumstances, it became necessary to impose some check on this increasing evil.

The Court of Examiners, anxious that students should attend teachers capable of giving them enlarged and scientific views of their profession, and not knowing how it could obtain from distant places any evidence of the teacher having himself received a liberal education, but by the means adopted; resolved not to receive certificates of attendance on anatomical lectures, but from persons appointed by an university, teaching in a school connected with, and accredited by, one of the recognized hospitals; or being himself a physician or surgeon to an hospital. Could better means of accomplishing the object been suggested, doubtless they would have been preferred. The supposition that the Court meant, by this regulation, to confine the teaching of anatomy to physicians and surgeons of hospitals, is absurd; for no person could give such anatomical lectures as it wished to be generally established, but those who have undergone a long and laborious education with this intention.

When the foregoing regulation was first made, the Court announced its intention of still admitting certificates from all those persons whom it had formerly recognized as anatomical teachers; and from unwillingness to act with injustice or harshness to any person who could urge a reasonable claim to become an anatomical teacher, it admitted others, and eleven anatomi-

cal schools were recognized in this metropolis. It is well known that the regular schools of anatomy have never been open, during the summer season, in this or in other countries. There are good reasons for believing that the summer courses of anatomy, and the great number of minor schools, have been injurious, by preventing the established schools from obtaining a supply of subjects adequate to the proper tuition of students.

The Court of Examiners was warned by its own members of the evil construction that might be put upon this regulation; and, therefore, urged to send to those whom it recognized as teachers a circular declaration of the seeming necessity for this restriction; and also a description of the lectures giving in London under the title of anatomical, expressing the hope that these acknowledged teachers would make their lectures as extensive as instructive, and that they would discountenance, as much as possible, the practice of teaching the common facts of anatomy without reference either to physiology or pathology. When the adversaries of the college first publicly charged it with being influenced in its conduct by sinister motives, a considerable number of the most respectable of the junior part of the profession addressed that institution, expressing their approbation of its constitution, and their conviction of the purity of its motives, yet accompanied by the wish that the regulations which had excited discontent should be revoked. They also urged the college to allow them to publish a declaration of their sentiments for more general signature, which, in their opinion, would soon shew that the malcontents were but a small, and probably a self-interested party. The college would not agree to any of these propositions: and it is not probable that men would be so indifferent about public opinion, or reject the friendly assistance offered them to regain general approbation, but from the consciousness of being undeserving of censure.

The Editor of the *Lancet*, and his coadjutors, had, however, for some time been inoculating the profession with suspicion and discord; nor did the virus fail to produce its expected effect among those susceptible of its operation; viz. those who thought they might derive advantage from an alteration in the con-

stitution or regulations of the college. The last act of the college was the assailable point, and its adversaries rushed forward to the attack with clamorous and furious hostility.

It would seem like mischief-making to repeat the accusations and calumnies that were brought against the college, which would be necessary in order to refute them, at the present juncture, when they are quickly fading even in the memories of those principally concerned in them. It would, moreover, be useless; for after all that could be said on the subject, persons will judge of others by themselves, and impute those motives to them which they are conscious would have influenced their own conduct in similar circumstances. Thus shame must become attached to those who think evil of others. Suffice it therefore to say, that the college revoked those regulations which were found to have produced dissatisfaction.

[To be continued.]

REMUNERATION OF THE COURT OF EXAMINERS.

To the Editor of the London Medical Gazette.

SIR,

You would oblige me if you could inform me, through the medium of your valuable publication, whether the 22l. 10s. which is paid on becoming a Member of the Royal College of Surgeons in London, goes into the private pockets of the Examiners themselves or not?

I am, Sir,

Your most obedient servant,

MEDICUS.

London, 20th Nov. 1829.

[The above letter was mislaid, otherwise it should have been inserted sooner. We applied for the required information, and the following is the answer—the accuracy of which may be relied on.]

“Twenty-two pounds, the price or fee upon a diploma (not 22l. 10s.), are carried to the account of the College funds, and do not go into the private pockets of the Examiners themselves; and it is only from this source that the funds of the College are derived, it having no landed endowment.”

107.—v.

PROTRACTED GESTATION.

THE discussion at the Westminster Medical Society, which we reported in our last number, was resumed on Saturday last, as follows:—

MR. JEWEL.—I rise for the purpose of relating two or three cases, which have occurred under my own observation. The first case I have already related to the Society, during some part of the last session: it was one, I imagined, of extra-uterine foetation. The woman was the wife of a mechanic, who took a situation in the country, and was separated from her husband. She obtained permission to come to town, and passed the night with her husband; the 8th of November. All the various sympathetic affections of pregnancy made their appearance, and at last she gave up her situation and came to town. A midwife was engaged to attend her. She had all the premonitory symptoms of labour, and even sharp pains, but these subsided, and no further parturient action took place. It was remarked by Dr. Locock, that in these cases of extra-uterine conception labour comes on at nine months, and in this case it took place on the 273d day.

The other case bears more on the question. It was one of a woman whose husband was a labouring man, and was obliged to go 40 miles from town. He was a well-digger. This woman remained in London, and some good-natured friend suggested that her husband might have got another wife. She went to him immediately. When she arrived, her husband received an order to go 20 miles further on, to some other work. She staid there only one night with him. This was on the 15th of March, and she fixed the 15th of December for her delivery. I was anxious to ascertain whether labour would come on at that time. The labour took place, not on the day she fixed, but the following day, the 16th of December. Now these are facts from which we might, perhaps, draw some inference, that the period of gestation is nine calendar months. Reasoning from analogy, we find that nature sometimes deviates; but, I believe, if we take into consideration these facts,

we shall find that she does not deviate in any great degree.

There is one circumstance which I wish to notice. I think we should receive with great caution the accounts of authors and writers on this question, because some of them may be misled by the reports they receive from women themselves, which can seldom be relied on. For instance, Capuron, a man of great talent and observation, states, that a woman was delivered of a living child at 4½ months, and that the child was reared. Now, he must have relied on the statements made by the woman. And there is a case alluded to by Dr. Paris, where a woman was delivered at the 16th month. If we rely on the statements we usually receive from women, we shall generally be led into error.

MR. CHINNOCK.—From being officially connected with an institution, I was applied to to give evidence on the Gardiner peerage case, relative to a supposed instance of protracted gestation, which occurred in my practice. Some legal objection was made to the case, and as the particulars have not yet appeared, I shall state them.

A young woman applied to me in the month of October to attend her in her confinement, stating that it would take place in January following. Finding no symptom of labour at the time she expected, I questioned her as to the mode of her reckoning, and her answer was, that she had not had connexion since the 29th October preceding, when her husband went to join his ship. She had menstruated 14 days before. On the 20th day of February she was delivered. Thus making a space of 298 days from the supposed time of conception, 18 days after the usual time. It is right that I should observe, that labour came on three days previous to delivery. Perhaps, it may be argued, that this is not a case of 298 days' pregnancy, but of 295, from the uterus shewing a disposition to get rid of its contents three days before. I have counted from the hour her husband left her, and it is not certain that conception may not have taken place any day previous.

Now I submit this as a clear case of protracted gestation. But it was not admitted by the Solicitor-General, in consequence of my drawing the conclusion from the statements of the patient,

and not from actual observation. If the statements of a virtuous woman are not to be relied upon, I would ask, what is to guide a medical man—how is he to judge—how is the question to be settled?—unless we were to establish an experimental hospital, as proposed in a jeu d'esprit, by Dr. Lyall.

Let us compare the medical testimony. On one side, we have the names of Clarke, Gooch, Davis, Blegborough, and Pennington. I grant you they gave evidence in the negative; but the cases they bring forward tend only to prove what has been admitted on all hands—that the *usual* term is nine calendar months; but they do not disprove the probability of gestation being protracted.

On the other side we have Merriman, Granville, Conquest, Blundell, Hopkins, and others, who bear their personal testimony in opposition to these; and they bring decided proofs as to the possibility of nature varying in her time;—and I do conceive that one well-authenticated case is better calculated to bear on the subject than one hundred that are theoretical.

DR. LEY said, the possibility of protracted gestation cannot be denied. The question is, as to the frequency of the protraction, and the utmost extent to which it has gone. It is a question of experience, and can be determined only by an examination of the facts. But before we enter on this subject, we must first determine the *average* period. As far as I have seen, the assumption has been universal, that the period is 280 days, or nine calendar months. I believe nine calendar months approach nearer the truth than 280 days. I would first take the authority of the church: Christmas and Lady-day falling on the 25th December and 25th March. I might also quote regal authority on this subject—if it were proper—for it is well known that an illustrious personage was born exactly nine calendar months after the royal parties met, and they cohabited only once.

I am inclined to think that gestation can be protracted, and the only point of importance is to determine the extent of that protraction. This is the most important point of all connected with legal investigation; because no one would assert that a child, born nine calendar months and four days after the death of the reputed father, would not

be allowed to inherit, supposing him to have died suddenly, and in the full vigour of life. But when the question comes to fourteen days, three weeks, or a month, it assumes a different shape. Then it can only be determined by a reference to facts. But there are great difficulties attending this subject, because we do not know at what intermediate period between menstruations conception has taken place. Some women have gone beyond the nine calendar months; and because they have gone three weeks beyond the average period, they must have proved with child immediately before the last menstruation. I recollect an instance in which a woman went more than eleven lunar months; but surely this is capable of another explanation, and if it is explicable on other principles more consistent with the phenomena of nature, we must adopt that. But that protracted gestation does take place, I have no doubt. A patient, whom I had attended more than once, and who had never been mistaken above two or three days, begged me to attend her. She passed the utmost period that could be allowed; she passed *eleven* periods. I was disposed to ascribe this to an accident, but I found certain circumstances which struck me forcibly; it was, that the maturity of the child seemed to be delayed by a peculiarity of structure. The labour had advanced considerably when I was called. I first thought it was a dead child, because I found the bones riding one over another. But, however, a child, far behind the usual development, was expelled; it cried like a premature child. After the birth, pains came on, but the placenta was not expelled; and I then passed my hand, and found an after-birth, not larger than three inches in diameter, terminating in a line two-thirds of an inch in thickness. There was morbid adhesion of the placenta. This case was to my mind one of the strongest proofs of protracted gestation. We had not only the fact, but the explanation of the phenomenon. The extent to which labour can be protracted is not yet settled; no case has yet occurred to me where I could say the labour was protracted beyond fourteen days. The strongest argument after all is that drawn from the analogy of the lower animals. It is not yet settled in the human species; and it is not likely,

from the nature of the evidence, that it will soon be so.

DR. RYAN.—I take the liberty of making a few observations on the important subject before us. The weight of medical authority in this, and in every other country, goes with Dr. Granville, whether we look to ancient medicine or the present state of medical science. There are cases which have not been alluded to. There is one by Dr. Collins, of Liverpool, in the *Edinburgh Journal* for 1826, in which it appears the woman went eleven months. It happened subsequent to the Gardiner Peerage cause. Dr. C. had no theory on the subject; he merely stated facts. There is another case, published by M. Velpeau, where the woman went 310 days.

I have met with a case of this description subsequent to the Gardiner Peerage cause, and which I have placed on record. I was requested to attend a patient, 21 years of age, who married in January 1826. She had menstruated previously with great regularity, and she menstruated the last week of February 1826. She quickened in July, and she expected to be delivered in November, about the ninth calendar month. She was not delivered in November, nor in December, nor in January, and she went to the middle of February. Now this case may be disputed by some gentlemen, but the delay alarmed her friends so much that they expected she would have died undelivered. She had no object in giving an untrue account of herself. Hippocrates, and all the older writers, relate cases where pregnancy was protracted for many months beyond the usual period of gestation; and practitioners must every day meet with cases where women must mistake very much, or have protracted gestation. Dr. Ryan added, in answer to a question from the chairman, that his patient reckoned from the last menstruation, and she had always before menstruated regularly.

DR. GRANVILLE'S reply.—Sir: the experience of the first evening, when I introduced this question to the attention of the Society, and that of this evening's debate, convince me of the propriety of the line I adopted in reserving all I had to say in reply, either to questions or observations addressed to me by the various speakers, until the conclusion of the discussion, rather than interrupt it by interlocutory dialogue, which,

without promoting the investigation of truth, debars gentlemen well skilled in the subject-matter from delivering their sentiments at length; while it tires and exhausts the patience of the hearers. I will be bold to say that by following such a line of conduct in our discussions, we shall, at all times, elicit more information than where gentlemen offer themselves to the attention of the Society with controversial remarks more than once, except in explanation.

That we have derived as much benefit as we could desire on the present occasion, from this mode of conducting the discussion, is a fact fully established by the several speeches from distinguished members, which followed each other in succession on both evenings. The Society is much indebted to those gentlemen, for their exertions in throwing light on a question of the utmost importance; but more than any other am I indebted to them for the earnestness and zeal with which they have assisted me in developing its merits, smoothing its difficulties, and establishing its truth.

Although I may say that with regard to the principle itself all the gentlemen who followed me seemed to be in accordance, there are differences of degree, trifling indeed, but still differences between us, of which I am probably expected to take notice, and observations to which I am ready to reply. I shall endeavour to do both as briefly as the nature of the subject will admit; and for this purpose, instead of following each of the speakers methodically, I shall confine myself to those among their remarks which bear being grouped together, and answered collectively.

Here I must again crave the indulgence of the Society, if, contrary to my usual practice, I refer to my notes for the principal part of my argument. The reason of this is obvious. In the trial to which such frequent allusions have been made, and with the whole tenor of which the Society must by this time be well acquainted, it will be recollected that I was put foremost in the battle among those who with me supported the doctrine of protracted gestation; not that my character, age, or experience, pointed me out for that situation, but because I alone brought forward registered and well-digested facts—not facts resting on memory, but facts recorded as they occurred during

a long succession of years, when there could have been no purpose to serve but that of promoting scientific investigation. Such being the case, it is manifest that I need be on my guard in what manner I controvert whatever has been opposed to me in the way of observation or argument in this inquiry, not on this occasion—for I am happy to find we are all agreed—but on the occasion of the trial in question, not only by the medical witnesses on the other side, but by the learned gentlemen who summed up their evidence and commented upon our own. I must be cautious and circumspect in my expressions, lest, as I see sundry pens at work ready to waft to the public all that I have to say on this subject, I should unwittingly expose myself to some unwelcome *ex officio* information, for which I am neither prepared in purse nor person.

In the first place, then, I would notice the remark which fell from Dr. F. Ramsbotham, who stated that nothing which I had advanced the previous evening proved satisfactorily that *human* gestation could be prolonged to any extent. There is evidently a misapprehension on the part of the learned Dr. in this place, for I never said that gestation could be prolonged to *any* extent, but I contended that protracted gestation, as an occasional exception to a law of nature, was possible, and brought forward cases to prove it, to a limited extent of six weeks at most, but oftener only of three, four, or five weeks. There must be a limit even to the range of exception. For instance, what would my learned friend say of me, were I to deny the possibility of a human monster with two heads having existed—as an exception to the general laws of formative nature, or of two Siamese youths being linked together by a fleshy band, only because my learned friend could not prove also that there ever existed a lady with a pig's face?

Again, Dr. Ramsbotham, being anxious to develop an ingenious supposition of his own, respecting a prolonged intro-tubal existence of the foetus, seems to insinuate that *protracted gestation*, in my opinion, is referable to *utero-gestation* only, and to that opinion he objects. I have purposely abstained from even using the word *utero-gestation*, because as I am totally ignorant of the real causes which may protract gestation, so am I at a loss to state in what

part of the uterine system gestation is retarded. But I will forgive my friend these little misapprehensions on his part of what I have said, for the sake of his ultimate admission, that protracted gestation is possible from analogy derived from comparative anatomy, and still more from his notion that the foetus may on some occasions be supposed not to begin his nine months' career till he has spent some days on his road from the ovarium to the womb. The question between us is one of manner, not of reality. It imports me not to know whether an idle boy, who has reached home some hours too late, did so in consequence of loitering when he first started from school, or only when he was nearer to his home, if the fact of his idling by the way be admitted.

Some gentlemen asked whether I could explain the reasons, or in other words, account for protracted gestation—and another member put the question, whether any correct information had yet been obtained respecting the immediate cause of parturition.

Now I would reply to the former query by a negative to the latter. It is because, as I observed on the former evening, "we are not acquainted with the marvellous action that comes on at a particular time to expel the child," that we can neither fix a time for the more natural period of parturition, nor deny the possibility of that period being protracted.

Doctor Locock, who after some very sensible remarks on this question, concluded with assenting to my proposition, that the period at which parturition naturally occurs, will occasionally be put off;—asserted, that the result of extra-uterine foetation proves that nature has a fixed rule in human gestation. Now, although I admit myself the existence of a fixed rule, and only contend for an exception, I do not agree with him in the proposition, that because the extra-uterine foetus is said to die at the nine months' end, and cannot go on increasing, the limitation to gestation is therefore established. I would ask in answer to that, is there nothing else to account for the death of the foetus? May not the unnatural situation he is placed in sufficiently account for his destruction? But to this argument of mine I attach no importance; I am satisfied with the impression en-

tertained by the learned physician of the possibility of protracted gestation.

Among those who spoke this evening I would beg leave to confine myself to the arguments of Dr. Ley, not from want of due regard to what fell from other gentlemen, but from a desire to save the time, and be sparing of the forbearance of the members present. Dr. Ley is surprised that I should have discussed in preference, and limited myself to, the question of the possibility of protracted gestation. The extent, says the learned Doctor, of protracted gestation, is what imports us most to know. Truly it is so, but in my case I had first to prove that protracted gestation was possible, as the occurrence of such a phenomenon was declared by the physicians and learned gentlemen on the other side to be impossible. What said the Solicitor General on that occasion? "we have examined the most eminent practitioners in this country; their lives have been devoted to the study of the history of the human foetus (!!) They say the period is invariably uniform; they believe an extension of the period to be *physically impossible*." Surely, sir, after hearing this, my friend Dr. Ley will no longer doubt of the necessity of my first applying myself to demonstrate the *possibility* of that which was contended to be impossible. The question of extent to which protracted gestation may reach is doubtless of the utmost importance, but far other arguments and inferences would be required to settle that question. In all his other statements I cannot but agree with Dr. Ley, and I thank him for his valuable authority, in addition to the overwhelming one already collected before the Society.

Another part of my duty in summing up this discussion is to refer to the cases brought forward as new instances of protracted gestation, in corroboration of my proposition, both on a former and on the present evening. And while I thank those gentlemen who have done so, and particularly Mr. Chinnoek, Dr. Ryan, and Mr. North, the latter of whom I was happy to find fighting skilfully by my side, and parrying one or two slight blows aimed at me on a former evening; I cannot but impress on the attention of the society the fact, that when we come to consider a question of such

importance as this among really practical men, we find nothing but affirmatives and cases in illustration.

But then, sir, these cases will be disputed, either in the way that Dr. Merri-man very properly noticed, (and in noticing, duly castigated), namely, by forthwith suspecting the honesty of the female party; or, as I have myself before remarked, by doubting the judgment and ability of the medical persons who narrated the cases.

It is indeed a curious, and at the same time preposterous assumption on the part of those who are opposed to us, that no woman, it matters not of what character or degree, (particularly if married) and who has been quoted as a case to illustrate protracted gestation, has been admitted to be either correct in her notion of her own state of health, or honest in conduct. In fact, these gentlemen have contended that all married women who have gone more than nine months with child are worthless of credit; and that "unmarried women, who have applied for the assistance of the most eminent practitioners immediately after the indulgence of their passion, (such are the words of the Solicitor General), are alone worthy of confidence."

With regard to the very cavalier manner of handling the medical authorities who supported the possibility of protracted gestation by facts, registered, mind me, at the moment of their occurrence, and not recollected only at the moment of examination for a particular purpose—registered during many successive years—when there could be no purpose to serve; I have only to instance the way in which I had the honor of being treated by the gentlemen in flowing robes. It is curious that I have never been able to obtain, until some months after the publication of M. Le Marchant, which I hold in my hand, and which was lent me last month only, an account of the summing up of my evidence by the Attorney-General in the Gardiner peerage; that publication appeared so late as four years after the trial, or the men of law would, in all probability, have heard from me somewhat sooner.

I am aware that it is a well known trick in a counsel for either party to throw out insinuations against the witnesses of the opposite party; and therefore the society will not be surprised

when I read out of this book how Mr. Attorney-General began his comments on my evidence.

"The first witness," said the learned gentleman, "called to prove exception to the general rule, is Dr. Granville. I shall say nothing to his disadvantage." Delightful forbearance this in a lawyer, who knew that the whole life of that witness—his conduct while in the enjoyment of a good share of public consideration—and the testimony of some of the lords he was then addressing, would instantly have gainsaid the law-officer, had he ventured to follow a different course. Thank God! a physician's character and fair reputation in this town are not to be extinguished by a forensic or oratorical reticence, or by a figure of speech.

In supporting the possibility of protracted gestation before the lords, I acted conscientiously, and according to the conviction of my mind, brought about by the occurrence of facts collected with more industry than my opponents have been able to shew in the course of several years experience. And it is not less to the purpose to say, that in coming forward on that occasion I neither stipulated for a specific remuneration, which our opponents received, but which we have never; nor did I consult my interest when, in giving my evidence, I ran counter the family interest of several who had before been in the habit of consulting me professionally. For the forbearance, then, of the Attorney-General upon that occasion, I would offer in return the expression of my hearty wish that when nature shall have asserted her right, and the now exalted personage, after a long and illustrious career of honour and usefulness, shall be no more, there may be inscribed on his tomb, "Nothing shall be said to his disadvantage."

I will now, sir, grapple with one or two facts which have been disputed, because I shall be able to shew that if there be any endeavour to garble truth in cases of protracted gestation, it is on the part of those who dispute the facts, and not of those who relate them. On my part, and for our present purpose, I will select, if you please, the case of Mary Parker, brought forward by myself, and that of Mrs. Mitchell, brought forward by Dr. Hopkins; a case which my learned friend Dr. R. said was very

strong until it was explained by further examination.

Dr. Ramsbotham has repeated this evening what he had asserted before that the eminent practitioners who had been examined on the side opposed to us, had founded their opinion on many cases. I charge that learned gentleman who has no doubt read the evidence throughout and spelt it—I charge any other who may read it—nay, the eminent practitioners themselves, Dr. C. Clarke, Dr. Gooch, Dr. D. Davis, and, *inter alios*, Mr. Pennington, “whose lives, as Mr. Solicitor-General said, have been devoted to the study of the “history of the human foetus”—I say, I charge them to point out one only case brought forward by them in support of a doctrine so inevitably true and uniform in “thousands of patients who have been under their care,” in which a name, a date, a residence, or any other title to confidence and reliance have been mentioned? While we, who supported rare exceptions out of some thousands of cases too, exhibited these instances of exceptions, with every particular and minute circumstances of those exceptions noted in books by impartial observers, and even produced the parties themselves. One of those eminent practitioners, indeed, Dr. C. Clarke, *alluded* to numerous cases in which he could say safely that the period of 40 weeks had never been deviated from; but he merely alluded to them generally, and from memory, and could not undertake to say whether they were five, ten, or twenty. The unvarnished tale of Mrs. Parker is this:—

She is 41 years of age; applied at the Westminster General Dispensary on the 7th April, 1825, being in a state of pregnancy, when a proper midwife was appointed to attend her. By her account she had missed her menses upwards of eight months, and expected in one month to be confined—that is, in May. She was produced by me at the bar of the House of Lords, on the 4th of July, 1825, in a state of pregnancy still, having outran her reckoning by at least six weeks. She was examined at full length, in the strictest manner, and interrogated in every possible way that forensic ingenuity could devise. No witness ever gave a clearer account, or more pertinent answers. The Attorney-General (p. 316) admitted, that, after the cross-examination of this wit-

ness, and lopping off as much of her evidence as they could, she must have gone her full nine months at the time of her appearance at the bar; and this, says the Attorney-General, “shews the absurdity of relying upon such cases to assist calculation, and the necessity of examining into the cases stated by medical men.”

Well, what was in reality the result of this case of Parker, thus triumphantly concluded at the expiration of nine months by the Attorney-General himself, as if she had actually been at that moment delivered? Why, that she went nine days longer, and was actually not put to bed until the 13th instant; or in other words, several days after the said judges had declared that a woman could not go more than nine months. This appears, from the report of the midwife, perfectly authenticated. But perhaps, even here, our friends the lawyers will doubt the veracity of the patient, the midwife, and the physician, as it may suit their purpose.

Yet these gentlemen, who thus jump at conclusions which are shattered to atoms, and then wafted into nothingness by succeeding facts, venture to throw out this insinuation against us:—“It is the character of some men to adopt extraordinary conclusions, rather than to examine into the extraordinary appearances which afford them amusement and pleasure.”

So much for Mary Parker's case, which may now be fully recorded as a case of protracted gestation, on the authority of Sir J. Copley himself, when Attorney-General of England.

We will now analyse the case of Mrs. Mitchell. Dr. Ramsbotham, who followed me on this question upon a former evening, and who stated that such a case would have been sufficient to persuade him of the reality of protracted gestation, had it not been demolished by the evidence of other witnesses, will range himself on my side when I shall have shewn that the demolition of Mrs. Mitchell's case was like the demolition of those fiery castles with which the pyrotechnic exhibitions at Vauxhall generally terminate, to the delight of both lawyers and physicians, as well as babies and *id genus omne*; when, after many snappish rumbles and fuzzing noise, smoke and stench in abundance, and, lastly, a great explosion, the stout

frame or structure of the real castle remains behind unbattered, to serve for succeeding exhibitions.

My friend, Dr. F. Ramsbotham, gentlemen, it should be known, comes all the way from the East—from Broad-Street Buildings—for the sole purpose of assisting us in this investigation; and thither, all the way, must he return to-night. Now I should feel great satisfaction if I could induce him to become a more decided combatant on my side, by shewing him that the case which produced two such opposite effects on him, ought, in fact, to convince him of the truth of our doctrine.

The way in which facts have been strained, in Mrs. Mitchell's case, in order to make them come up to the bearing point, is worthy of notice. I, of course, acquit the gentlemen who handled her case so roughly of any sinister intention. Theirs was the pure desire of eliciting truth, no doubt; but the result has convinced me that it is somewhat dangerous to rely on conclusions squeezed out by special pleaders, from clear facts obscured by cross questions, or, as they might well be called, *cross purposes*.

Mrs. Mitchell deposes, that her husband, who was purser of the *Galatea*, was with her a fortnight, in the year 1798, and that the 6th of June was one of those days.

On this, the Attorney-General produces two registers from the Navy-Office; the one of which is called a ship muster-book, the other a book of the clerk of the cheques, to disprove her assertions.

The former register is generally signed by the purser, the other by the clerk of the cheques of the dock-yard. In the former, the name of Mitchell, purser, was read over, with all the rest of the crew, on the 7th, 14th, 22d, 31st May, and 1st, 14th, 21st, and 27th June. His own signature is to the book. Now the Attorney-General here jumps at the conclusion that Mr. Mitchell could not be with Mrs. Mitchell in York-Street, Westminster, and be at Plymouth at the same time too, according to the muster-book. But, lo! when the counsel on our side asks the clerk of the navy-office at the bar, whether Mr. Mitchell signed the said muster-book each time or day therein stated, hear what he says:—"The purser does

not sign to each muster, but he merely signs the book at the end."

"In your judgment, when does Mitchell's signature seem to have been affixed?"

"I see it is stated to be signed the 30th day of June."

So that, in reality, this very register, or ship's muster-book, proves nothing as to the presence of Mitchell on board the *Galatea* on the 6th June, or any day previous for some time; but just the reverse. Yet the Attorney-General, lacking his usual discrimination on that occasion, takes upon himself to say to the Peers—"Mrs. Mitchell pretends that her husband was with her the latter end of May, and the first week in June, in London; and eight times in each month has this man, Mitchell, actually signed, with his own hand writing, the muster-book;"—and this mind, sir, the Attorney-General says in despite of Mr. Lance, the witness from the navy-office, who deposes, on oath, that "the purser does not sign each muster, and in this case signed on the 30th of June only, once for all." (1)

The fact is, sir, that I can throw some light on this part of the evidence by the knowledge I must have of the practice in the king's ships, having been some years on board of them. The captain's muster in harbour, here alluded to, is little more than a farce, as far as the officers are concerned, and more so with regard to the purser, who is always supposed to go backwards and forwards for the victualling of the ship's crew, and has even a boat allowed to him, in large and well-regulated vessels, for that purpose; and when the said muster takes place, if he does not answer to his name, and no mark exists at the same time in the register, of his having an extended and official leave of absence of many weeks, he is never noted as absent. I have seen pursers and captains affix their names to the ship's books, once for all, at the end of one month and longer, very often.

The thing is, indeed, different with reference to the register of the clerk of the cheques, who goes on board to see that no more names of men or officers are borne on the book for victualling than there are persons actually on board. Now this register, and really official document, says that the clerk of the cheques was on board the *Galatea* May 26, 1st and 14th

1st and 14th of June, and so on: So that Mitchell on the shewing of this register might have been absent from the 2d to the 14th of June, which includes the 6th. On that day, therefore, it is *not proved* that Mitchell *could* not be with his wife; and that is the *terminus* of *conception* assigned by her, and we have no business with any thing else. Why not call some of the many who must yet survive—lieutenants, midshipmen, or others of the crew of the ship—to prove that Mitchell was *bonafide* on board on the 6th June? The clerk of the cheque's register itself does not prove it—far from it; and the first or ship's muster-book is good for nothing. But I will say more for the veracity of Mrs. Mitchell, whom I know not, and never saw even at the bar. Mr. Mitchell may have been absent from the ship even on the 1st of June, when the clerk of the cheque called over the ship's company, and yet his absence not have been noticed. The captain, it it appears, was himself absent on leave. If Mitchell was absent by sufferance from the first lieutenant, which has been often the case, no notice would be taken by the clerk of the cheques, who was probably told Mitchell was just then not on board; and thus we would have an interval of sixteen days clear, during which it cannot be disproved that Mitchell might have been with his wife, including the 6th of June, from which conception was dated; and thus is Mrs. Mitchell cleared of the foul aspersion of unchastity, and another case of protracted gestation added to our list.

But I have said enough, and more than enough, for my purpose, and for the instruction of at least the junior members of the Society, who may in their time and turn, perhaps, be called upon to give an opinion, for which they will be glad to have sufficient authority to guide them. To the senior members, and my equals in standing in the profession, I have only to express a hope that they will not hold me to be pedantic because I strove to be dogmatic, when facts arrange themselves on my side, and are multiplied by the observations of those gentlemen who so readily entered into the debate. Neither will the earnestness of manner into which I have this evening been betrayed, by the nature of my argument, be found out of place. To some, the discussion may, perchance, appear to have been unnecessary, on a ques-

tion so clear, and as regards principle undisputed by any gentleman present; but I have to plead to this the excuse of an ancient writer:—“*Tametsi hanc materiam esse arbitror perspicuam; tamen de illa dixi, quod apud vos plurimum debet valere.*”

[Dr. Granville sat down amidst the expressions of general approbation, and the meeting did not break up till considerably after the usual time. The discussions have altogether excited a very high degree of interest.]

MEDICAL GAZETTE.

Saturday, Dec. 19, 1829.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum alt, dicendi periculum non recuso.*”—CICERO.

MR. EARLE AND THE LANCET.

IF it can afford Mr. Earle any satisfaction to know that his letter to the Editor of the *Lancet* has proved “gall and wormwood” to that worthy, such satisfaction must be his. It is an old remark, and a true one, that cunning people often over-reach themselves; and Wakley's manœuvring on this occasion forms a very good illustration of the adage. But for his elaborate efforts to refute the charges of Mr. Earle, and but for the statements of his own reporter, as contained in a letter which now lies before us, we should never have known the extent of his sufferings; sufferings from which not even his persevering exertions in the “hue and cry” against Mr. Phillips, of Finchley, have altogether been able to divert his mind—unprecedented as such exertions are in the annals of medical literature.

Wakley knowing that there was no chance of his being believed by any one unless the truth of what he said was vouched for by others, immediately on the receipt of Mr. Earle's letter, applied to the parties whose names had been mentioned, to see how far he could get from them any thing that would bear out his assertions. This was exactly as we had anticipated, and actually foretold, three weeks ago, (*Gazette*, Nov. 21). How far he succeeded in this, we have

already partly shewn. Dr. Armstrong recollected nothing, a circumstance too well explained by his illness; Mr. Weekes would write nothing, though urged by Wakley to do so; and what Mr. Fay did indite was nothing to the purpose, for he admitted that he had made communications to Mr. Earle of the nature described by that gentleman, only with this reservation that he had not been authorised to do so. One evidence still remained to be adduced, that of his reporter; an authority, it is true, of doubtful value, as coming from one in the pay of the party to be defended. This individual, with generous and *disinterested* zeal, stepped forward in his patron's cause, prompted, as Wakley himself informs us, "solely by his own honorable feelings." Mr. M'Christie's letter was received within little more than forty-eight hours after the publication of Mr. Earle's, Wakley having "neither seen nor heard from him, nor held the slightest communication with him, directly or indirectly, upon the subject." So Mr. Thomas Wakley received a letter from Mr. Earle, on Monday, Nov. 16, in which he described various applications and asseverations as having been made to him by Mr. M'Christie, the reporter to the Lancet, deeply involving the character of the Editor; and he, the said Editor, held no communication, "directly or indirectly, on the subject," with his reporter, until the Sunday following, when Mr. M'Christie, prompted *solely* "by his own honorable feelings," wrote to Wakley on the subject. Thus very nearly a week passed between the receipt of Mr. Earle's letter and that of Mr. M'Christie, without the party to whom they were addressed taking any step to ascertain what had really passed between these gentlemen, even without his evincing any curiosity to know what the latter had to say in explanation of Mr. Earle's positive assertions: such is the boundless confidence of kindred souls, *that fully understand each other*. Why however a letter so much to the point, and which was received "within little more than forty-eight hours" after the publication of that which it was intended, not merely to answer, but to annihilate, should have been so long kept back, or what the object of the Editor may be, in so earnestly requesting us to believe that he had nothing to do with it,

"directly or indirectly," we must leave for our readers to conjecture.

Whether its delay was owing to the extraordinary increase in the number and value of other communications, or whether the original version was not quite agreeable to the reader, or any alterations were suggested not quite palatable to the writer, we cannot pretend to say, but certain it is that three numbers of the Lancet were allowed to intervene between the receipt of Mr. Earle's letter and the publication of the only *shadow* of contradiction it has yet received.

We call it a "shadow" of contradiction; and we now undertake to prove, not only that Mr. M'Christie's reclamation does not gainsay the statements of Mr. Earle, but that it affords the strongest confirmation of their truth.

The letter may be divided into two parts or sets of propositions; the first consisting of retaliative accusations against Mr. Earle; the second, of statements inadvertently, but unequivocally, constituting most damning charges against the Lancet;—charges which, as they are published by the Editor himself, without any qualification or dissent, we have a right to presume are absolutely true.

On the perusal of Mr. M'Christie's letter, we saw at once that it was "got up" for the occasion—an artful admixture of truth and falsehood; but as we could not, on our own authority, contradict statements said to have been made by Mr. Earle, we forwarded the paper to that gentleman, with a request that, if there were any misrepresentations in it, he would point them out. Sanctioned by Mr. Earle's written authority, we have to state—

That the assertion made by Mr. M'Christie, that Mr. Earle, having stated that he did not attend the meeting held by certain gentlemen at the Freemasons' Tavern, nor contribute towards any fund for preventing the publication of lectures in the Lancet, added, "that he was ready to make an *affidavit* of these facts, at any moment you (*i. e.* Wakley) might require,"—IS FALSE.

That the assertion of Mr. M'Christie, that Mr. Earle said "there had been rather a hostile feeling existing between himself and Mr. Abernethy, and that he would not have consented to be present on such an occasion,"—IS FALSE.

That the assertion of Mr. M'Christie, that the above, or any thing to the same meaning, "was conveyed to Bedford-Square, as requested by Mr. Earle,"—IS FALSE.

That the assertion of Mr. M'Christie, that Mr. Earle admitted him, "knowingly on his part and avowedly on mine, as your own reporter, to the hospital practice,"—IS FALSE.

That the assertion of Mr. M'Christie—"I most explicitly stated to him (Mr. Earle) that I had called on him of my own accord, and altogether without your (Wakley's) knowledge,"—IS FALSE.

That the assertion of Mr. M'Christie, that Mr. Earle said "he had pledged himself never to become a contributor to the Lancet,"—IS FALSE.

That the assertion of Mr. M'Christie, that Mr. Earle said he was under the necessity of declining to give his notes, because "he was sure an improper use would be made of his compliance in other quarters, if it were to get known,"—IS FALSE.

That the assertion of Mr. M'Christie, that he did not assign as a reason for wishing to be allowed to report Mr. Earle's Lectures, that they "were highly appreciated,"—IS FALSE.

That the assertion of Mr. M'Christie, that, on his saying, "Well, I am sorry for this," Mr. Earle answered, "So am I, but I could not do otherwise; and you may tell Mr. Wakley that he ought to feel for my situation,"—IS FALSE.

These are the chief circumstances in which the letter of Mr. M'Christie contains statements at variance with those of Mr. Earle; but there are others of minor importance, which we omit, as not bearing particularly upon the points at issue.

Now, setting aside the direct and positive contradiction thus given by Mr. Earle to the statements made by Wakley's hired reporter, we ask, is it probable that Mr. Earle, who was one of the first openly to denounce the falsehood and malice of the Lancet (see his Letter, Med. Gazette, Dec. 13, 1827), should so far have humbled himself as to offer "to make an affidavit," at any moment he might be required, to gain the favour of one to whom he had publicly given the lie? Is it probable that he would assign as the motive of any part of his conduct the existence of a

"hostile feeling" between Mr. Abernethy and himself; and thus make Mr. M'Christie his confidant on so delicate a point at the very time he knew him to be in the pay of his bitterest enemy? And, *a fortiori*, is it probable that he would have requested him to communicate to his employer offers and statements which, if true, must have made Mr. Earle the meanest and most contemptible of mortals? Is it probable that Mr. Earle would have said, that he had pledged himself never to become a contributor to the Lancet, and have addressed a letter to the Editor of that publication within a week? Is it probable that Mr. Earle would publicly denounce the Lancet in his class-room—then send a whining message to Wakley, that he could not help it, and that "as a man, he ought to feel for him;" and immediately follow this up by publishing a letter so uncompromising and decided as the one alluded to, and which was certain to bring down upon his head his wrath he is represented as so anxious to deprecate? Mr. Earle's own account is, that he said, "Tell Wakley that he ought to feel that in consequence of his former abuse and injurious misrepresentations, the marked difference in his tone since I have been fairly reported, compelled me to take this step—tell him my character was suffering from his praise." Such are the two versions of the story, and we must leave our readers to believe which they think the more probable.

The credit to be attached to some parts of Mr. M'Christie's letter, must depend on the comparative degree of weight which may be thought due to his assertions and those of Mr. Earle respectively, as some of them, such as the above monstrous improbabilities, refer to what passed when no one else was present. Other parts, however, are refuted by evidence which the writer of the letter will scarcely be disposed to call in question—that of Mr. M'Christie himself, as given on a former occasion. For example, when he speaks of Mr. Earle "admitting him to the hospital practice," knowing him to be reporter to the Lancet, he forgets that he was not "admitted" by Mr. Earle until he had made a statement just the reverse of that now adduced. Mr. Vincent and Mr. Earle having some suspicions on the subject, had determined to ascertain whether he had sent reports of the

hospital cases or not, when (Monday the 14th of April, 1828) Mr. M'Christie called on Mr. Earle, and this gentleman, in a letter published at the time (*Gazette*, April 19, 1828,) gives the following account of what passed—an account, be it remembered, which, till now, has remained uncontradicted:—
 “I was, however, spared the unpleasant necessity of calling for such an explanation by the gentleman waiting upon me this morning, and, unsolicited, making a solemn declaration that he had never, in the whole course of his life, written a single hospital report. In reply to my inquiries respecting his being *bona fide* a medical student, *he distinctly avowed that he had always intended to follow the medical profession, and had entered himself as a pupil PURELY for the purpose of prosecuting his studies.*”

Again, Mr. M'Christie denies that when he called upon Mr. Earle to request his notes, he said the lectures were highly appreciated; but he admits that he said, “they were liked by the students;” so that this, which is put forth as a contradiction to Mr. Earle, after all amounts only to a slight difference as to the degree of estimation in which the lectures were held. Mr. M'Christie is also scandalized that Mr. Earle should use the word “enmity” in describing the sentiments expressed of him by Wakley, which he protests never fell from his (Mr. M'Christie's) lips, yet he had half a dozen lines before acknowledged himself the bearer of a message from Wakley to Mr. Earle, in which the *worthy* Editor expressed his regret for the “hostile feelings” he had entertained towards him. Thus, according to this very scrupulous gentleman, Mr. Earle's lectures were “liked,” but not “appreciated,” and Mr. Wakley entertained “hostile feeling,” but not a jot of “enmity:”—despicable quibbling!

Mr. M'Christie says, he told Mr. Earle that he came without Wakley's knowledge; Mr. Earle positively denies this, and states, on the contrary, that the circumstances were such as warranted him in concluding that Wakley did know; because, as appears by Mr. M'Christie's own showing, he had before been employed by Wakley to communicate a message to Mr. Earle; and it is a curious circumstance that on this occasion, although the reporter asserts that his visit to Mr. Earle was without his employer's knowledge,

he thought it necessary immediately to communicate to him the failure of an application made without his concurrence. “You will remember (says Mr. M'Christie in his letter to Wakley) that I called on you on the same afternoon *after* I had been with Mr. Earle.” But we are now insensibly passing from the charges against Mr. Earle to the indirect admissions of Mr. M'Christie, of a nature most unfavourable to the honesty of his employer; and to these we now direct attention.

When Mr. M'Christie became reporter to the *Lancet*, he says, “I called on Mr. Earle, aware of his having complained of the manner in which he had previously been reported to state that *I* (I in *Italic*) had had nothing whatever to do with those reports.” From this we learn, that statements had been published in the *Lancet*, concerning Mr. Earle, which Mr. M'Christie thought so discreditable that he felt it due to his character to disclaim having had any connexion whatever with them. Next, we have the motive which led to the publication of the said reports. “Further,” continues Mr. M'Christie, “that you (*i. e.* Wakley) considered Mr. Earle's avowed hostility against the *Lancet*—his attendance at the meeting at the Freemasons' Tavern, on the occasion on which Mr. Abernethy was in the chair, and his treatment of his patients in the hospital, as public conduct, and fair subjects for criticism.” Thus, then, did Wakley himself, in explaining to his reporter the workings of his mind, represent Mr. Earle's opinion of the *Lancet*, and his supposed attendance at a certain meeting as connected with the reports of his hospital cases!!! Farther—Wakley being informed that Mr. Earle had not attended such meeting, his reporter was instructed to express to him the Editor's regret for the hostile feeling “entertained against him in consequence,” with the addition, that if he would point out cases the publication of which “he thought would be conducive to his reputation,” they should appear. It is a remarkable fact that Mr. Earle, who is now represented as having made such despicable efforts to gain the favour of the *Lancet*, is stated with singular inconsistency to have spurned this conciliatory offer, for (says Mr. M'Christie) “he repeated his assurances that he only wished to be impartially dealt with.”

No art can stand against the simple

truth, and we pity alike the head and heart of the man who can read the monstrous absurdities which Mr. M'Christie's letter contains, without feeling to what disadvantage they appear when contrasted with the plain, straight-forward, and consistent narrative of Mr. Earle. Mr. M'Christie complains of Mr. Earle not having related *all* that passed: "he must have felt," says M'Christie, "that it would have been unpleasant for him to have stated the whole." That Mr. Earle has described all which ever passed between them, having the slightest relation to the points in question, he positively affirms; and we believe him. But we beg to ask, has Mr. M'Christie no recollection of ever having made any communication with regard to persons connected with the *Lancet*, which "it would have been unpleasant for him" to have had stated?

We trust it is the last time we shall have to wade through the trickery and falsehood with which the Editor of the *Lancet* has attempted to deceive his readers, with regard to this as well as every other question where concealment is necessary for his purpose. We, therefore, crave indulgence for a few words more, in reference to points in which the employer and *employé* are at issue. The Editor of the *Lancet* says, (No. for Nov. 14th, 1829,) "It is not true that we have urged, either directly or indirectly, that we are sensible of having injured Mr. Earle unjustly." If this be so, how is it that he sent the following message to Mr. Earle through the mouth of his reporter?—a fact which does not rest upon Mr. Earle's authority, but upon that of Mr. M'Christie, and which is admitted in this same letter, the accuracy of which is tacitly acknowledged by Wakley himself, who publishes it as a correct representation of what passed between them. Mr. M'Christie states, that when he told Wakley that Mr. Earle had not been at the meeting alluded to, he was instructed to say to Mr. Earle, "that you (*i. e.* Wakley) had certainly been labouring under a mistake on that point, and therefore felt sorry for any hostile feeling you might have entertained against him in consequence!"

Again, says Wakley, "It is not true that we have either directly or indirectly expressed a desire of making him some reparation." — (*Lancet*, Nov. 14th.)

Compare this with another passage contained in Mr. M'Christie's letter to Wakley:—"You farther said, that as I was about to take upon myself the duty of reporting, if Mr. Earle would point out to me one case or one hundred cases deserving of publicity, or the treatment of which he thought would be conducive to his reputation, you would publish reports of them." Thus did this *respectable* Editor, who never "directly or indirectly" said that he had injured Mr. Earle, and who never "directly or indirectly" expressed a desire to make him reparation, send his own reporter to say that he was "sorry" for the "hostile feeling" which he had entertained towards him, and to offer to publish such cases as he "would point out," as likely to be "conducive to his reputation;" in other words, to make an apology for the past, and to promise amendment in future.

It may, perhaps, be remembered, that when Mr. Earle stated, that though the reports were sometimes correct, the comments made upon them were false and malicious, Wakley tried to father these last upon a second reporter: a paltry subterfuge, which we at once detected, and, in consequence, declared the reporter to be "a nonentity." Well, then, in the letter before us there is a passage which throws some light on this point. Mr. M'Christie, in reference to the identical comments, the authorship of which had thus been denied by Wakley, writes thus:—"You gave me liberty to apprise him (*i. e.* Mr. Earle) that *your* observations had undoubtedly been made on the reports!" It is inconceivable that Wakley should have been so blind as not to see the mischief which this letter, giving the lie in this direct and repeated manner, must inevitably do to the character of his publication—if, indeed, it has yet any character to lose.

As to Mr. M'Christie, we can assure him that his conduct, if it be not "liked," will at least be "appreciated;" and we advise him forthwith to retire into the obscurity from which he has on this occasion, so unhappily for himself, emerged; or, if called upon to explain the circumstances which induced him so artfully to misrepresent the character of one to whom *we know* that at no distant period he voluntarily laid himself under personal

obligation, we recommend him to urge, like the apothecary who sold poison to his employer—

“ My poverty, and not my will consented.”

Nor would we have him disturb his peace by too much sympathy for Mr. Earle; for though he tells us that Wakley was “in a tremendous rage,” and that the circumstances “would call forth observations, such as he had hoped would never again have been seen, on his (Mr. Earle’s) conduct,” still it is just possible that the “rage” of his patron may not be quite so “tremendous” to others as it obviously is to him. As to the anticipated abuse of Mr. Earle, we have no doubt he is right; and only hope the worthy churchwarden will not be restrained by any of his usual delicacy, but give free vent to his feelings. Let him have recourse to invective, the usual evacuant of a baffled opponent, and the consolation of which he has already so often experienced. Nay, we advise him not to be disheartened, but to reiterate his “observations” again and again, regardless of their refutation: a drop wears even stone, by the frequency of its stroke; and as there are some fools in the world, the mere repetition of his assertions may in time make an impression, which individually they could not effect even on the weakest of his readers.

DEATH OF DR. ARMSTRONG.

It is with much regret that we have to mention the death of Dr. Armstrong, which took place at his house in Russell-Square, last Saturday. Dr. Armstrong was well known to the public, both as an author and a lecturer, and his premature decease affords a melancholy instance of a man cut off in the prime of life, and in the midst of a most successful professional career.

ANATOMICAL EXAMINATION OF THE DOUBLE FEMALE INFANT, RITTA-CHRISTINA.

THE body of the double female infant, Ritta-Christina, of which we published an account some weeks ago, (*Gazette*, for October 10th,) has recently been examined by a commission of medical men in Paris, and the following account drawn up by M. Geoffroy St.-Hilaire:

The first observation we made was, that Ritta had remained much more emaciated than Christina, at least in the portion of the body which evidently belonged to her, that is to say, the upper region, for the difference of these two beings was much more manifest towards the upper half, and their blending became more intimate as the lower parts were approached. Two anuses were recognised externally in the posterior part of the raphé, one on the right, the other on the left. According to the account of the nurse, the fæces were never evacuated except by that on the right, and, in fact, as we found in the sequel, this last alone communicated with the rectum, the other being the orifice of a canal opening into the vagina. The twins were united as two prisms might be, and had one pelvis with single apertures, but formed in some sort of two, joined vertically. The sensations produced in one leg were not perceived, except by the cerebral centre of one and the same head, as verified by MM. Larrey and Ribes. There were two hearts, but they were both enclosed in one pericardium. They touched at their points for an extent of 6 or 8 lines, in such a manner that that of Christina pressed upon and constrained the movements of that of Ritta: there was thus a heart on the left side, and another on the right. From their position resulted the trouble observable in the circulation of Ritta, and this circumstance explained the commencement of morbus ceruleus which had been remarked in her. There was only one liver, but obviously formed of two blended together, for there were two lobes of Spigelius. There were two stomachs, two small intestines, and those inferiorly were united into one. There were two uteri, one situated in the usual manner behind the bladder, the other quite behind, separated from the former by the rectum. There was one pectoral cavity, completely divided by one mediastinum, and separated, it is true, from the abdomen by a simple diaphragm, but at the middle the junction of two primitive diaphragms was recognised. Each might, therefore, have had its own particular side of the diaphragm, and M. Serres attributes to this the immediate cause of death, viz. paralysis of this muscle — paralysis which at first existed only on the side of Ritta, but which had extended to that

of Christina. As to the two hearts, nothing decided had been made out during life; the stethoscope indicated but one. Farther particulars are promised.—*Lancette Française*.

HOSPITAL REPORTS.

ST. GEORGE'S HOSPITAL.

Case of Scirrhus of the Pyloric Half of the Stomach.

THOMAS KENRICK, ætatis 70, a smith, residing at Knightsbridge, was admitted, Sept. 9th, 1829, under the care of Dr. Chambers.

His frame was emaciated; his complexion rather sallow; and the expression of his countenance of an anxious cast. He complained of loss of appetite, occasional pain in the stomach, and vomiting soon after eating, especially if his food consisted of meat or solid matters. The vomiting was not constant or regular, but would disappear for two or three days at a time, and again return. He suffered from eructations of air upwards, but never, according to his own story, could discharge it per anum. The pulse was weak; skin cool; tongue moist, but rather white; bowels tolerably open, without bulky motions; urine free, and high coloured.

On examining the abdomen, a circumscribed tumor, not prominent nor visible externally, was felt immediately beneath and to the left of the umbilicus. Its margin was tolerably defined and circumscribed; its consistence hard; its surface flattened; its extent greatest in the transverse direction, in which it might have measured some three or four inches. Towards the left it could be traced much higher than on the right side, and its upper edge, or termination, was less abrupt than that below; its inferior margin, which was semicircular, and had much of the sweep of the great curve of the stomach, was more rounded and more free than the superior; it was slightly tender on pressure, and moveable to a certain extent.

The patient stated that three months before his admission his health was unaffected; but soon after that period he began to be affected with loss of appetite, flatulence, and vomiting. He observed no tumor until three weeks before admission, when it was more beneath the left false ribs, but had subsequently undergone very little alteration in size. During the last fortnight he had vomited less; he never had hæmatemesis; knew no cause for his complaint; and had only drank "as much spirits as were necessary."

Little doubt was entertained of this being a case of scirrhus of the stomach; and the low situation of the tumor, to the left of the

umbilicus, appeared to point out the cardiac end of the organ as implicated. The following treatment was employed by Dr. Chambers:—

R Calomel, gr. v. Ext. Coloc. c. ℞ss. hac nocte.

• Haust. Salin. c. Magnes. Carb. ℞i. Tinct. Humuli. ℞ss. ter die. Broth, or milk diet.

On the 15th, the bowels being confined, he was ordered the calomel pill, as before; and on the 18th he is reported to vomit immediately after taking his food, which comes up mixed with acid; much flatus upwards: bowels open.

R Acid. Hydrocyan. (Medicin.) ℞i. Aq. distill. ℞j. ter die, intermissis alijs.

21st.—Much the same, save that the vomiting is not so constant. Bowels confined; looks much thinner.

Ol. Ricini. Aq. Piment. aa 3vi. Postea pergat.

On the 25th the dose of the prussic acid was augmented to two minims thrice daily; and on the 28th we find that he had had no evacuation from the bowels for two days; that he vomited some brownish poultice-like matter after breakfast, of an acid odour, and accompanied with a sense of burning in the region of the stomach. Pulse 58, small; skin cool.

Augeatur dos. Acid. Hydroc. med. ad ℞iij. in sing. haust.

Enema Oliosum statim et omni vesp. donec alv. respond.

Equal parts of Soda Water and Milk for ordinary diet.

Oct. 3.—Vomiting did not return after the 29th until yesterday afternoon.

Sinapisma Epigastrio. Pergat.

5th.—The vomiting and pain in the stomach are now very violent; the flatulence distressing; pulse 66, and very weak; skin clammy and cool; emaciation much advanced. The bowels acted after the enema with little feculent matter; urine high coloured and clear.

R Digital Pulv. gr. ½

Hyd. Ozymur. gr. ⅙.

Opii Pulv. gr. ¼.

Conf. Ros. q. s. ut ft. pil. ter die sumenda.

Rep. Enema ampulum omni vesp.

The vomiting was slightly relieved for a day or two, but again returned with as great severity as before, and much griping of the bowels. These symptoms increased so much that it was necessary to discontinue the pills above prescribed, and to substitute for them some hydrargyrus cum cretâ, and extract of poppies. On the 19th, being anxious to

leave the house, apparently from dread of dying within its walls, he was made an out-patient. Prior to his departure the poor fellow expressed a wish to be examined after death, as he said that he was certain his disease was mortal. He was at this time much thinner, and more debilitated than he had been upon admission; the vomiting was more constant and distressing; the pain in the tumor occurred in longer and severer paroxysms; in short, it was melancholy to observe the rapidity with which the disease was advancing.

He attended, we believe, for a short time as an out-patient, but some three or four weeks ago we were requested to see him at his own residence, as he was no longer able to quit his bed. We found him in a miserable state; emaciated to the utmost degree; vomiting instantly every thing he took, whether food or medicine; suffering from paroxysms of the most racking pain in the stomach or tumor; harassed with cough of an asthmatic character; and altogether reduced to the brink of the grave. As his nights were especially dreadful, we gave him strong doses of narcotics, with alkalies; and directed him to take arrow-root, with wine, in small quantities at a time, and as often as his stomach would bear it. Under this treatment he rallied surprisingly, and during the last fortnight of his existence he suffered comparatively nothing. His vomiting disappeared; the pain was greatly mitigated; in fact, was scarcely felt; his days were comfortable, and his nights no longer sleepless. The acidity on the stomach was removed, and the passage to the grave was smoothed, though of course no ultimate check could be given to the disease. He gradually became weaker; his intellects grew confused; and very early on the 4th of the present month (December) he expired.

We examined the body that day in the presence of Dr. Seymour, Mr. Babington, and Mr. Bushell.

The emaciation was extreme; the tumor, which had never changed its situation, and scarcely, if at all, augmented in size, was slightly visible externally, but readily felt.

On opening the abdomen, the disease was seen to be seated, as was thought, in the stomach. The pyloric half of this organ occupied exactly the situation of the tumor, and the pylorus itself was on a lower level than the umbilicus, and rather to the left. The parietes of the abdomen were not in the least degree adherent to the stomach, but the omentum majus was shrivelled up to a knotty mass, not a quarter of an inch in breadth, which cemented, as it were, the transverse arch of the colon to the great arch of the stomach. Independent of this connexion, there were no preternatural adhesions of the stomach to any of the neighbouring parts, nor any inflammation of them or of the peri-

toneum. On opening the stomach along its lower curvature the pyloric half of the viscus was found to be thickened, firm, almost cartilaginous in its section, and presenting the usual characters of scirrhus of the stomach. The distinction of the coats was not lost, but each appeared to be separately affected with the disease. The thickest portion was about the pylorus, where the diameter of the diseased coats was about a third of an inch. From this the disease diminished gradually as it formed towards the cardiac end. No unequivocal ulceration of the mucous membrane, or indeed of any other part, existed. The pyloric opening was narrowed; the duodenum was perfectly healthy; so was the œsophagus opening into the cardia.

The liver, mesenteric glands, pancreas, kidneys, colon, &c. were healthy. The abdominal aorta presented a few osseous scales, but on the whole was very healthy considering the patient's age.

The contents of the thorax were remarkably sound.

The head was not examined. Δ

SUSSEX COUNTY HOSPITAL.

Large Hydrocele.

SAMUEL MURRELL, ætat. 46, a strong muscular man, was admitted into this hospital with a swelling of the scrotum of four years' standing. Upon examination, an undulating feel was perceived. The circumference of the tumor was 26½ inches. The operation of paracentesis was performed, and about 56 ounces of watery fluid were drawn off. A dose of house physic was administered, and the part to be rubbed with Ung. Iodinæ 3j. mane et nocte.

Nov. 19th.—Going on well; complains of no pain.

This is a case of some interest, as it shows to what an extent the scrotum is capable of distention.

LITERARY INTELLIGENCE.

Dr. Conolly, Professor of Medicine in the University of London, is preparing for publication an Inquiry concerning the Indications of Insanity.

NOTICE.

A Well-wisher has our best thanks. The circumstance to which he alludes had attracted our attention, and been acted upon.

ERRATUM.

In our last, p. 335, for "spatio octo durum," read "spatio octo dierum."

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

LECTURE XIII*.

Mortification—its Divisions and Treatment.

THE next subject, Gentlemen, of which I have to speak, is mortification. Mortification is the death of a part, that is, of a part only; the death of a part with a peculiar change of structure in it, the result of a previous and peculiar vital action. By this latter circumstance mortification is distinguished from simple death—as in the case of an amputated limb, or from the temporary suspension of vital action, as when parts are frost-bitten; or from putrefaction, which frequently takes place after mortification has occurred, but which is by no means essential to the process; and, indeed, some kinds of mortification are to be considered as complete preservatives against putrefaction. It is also to be distinguished by the same circumstance from the chemical decomposition which is produced by heat, or the application of various chemical agents to a part of the body.

Mortification, gangrene, and sphacelus, are terms that are used nearly indiscriminately, yet perhaps there are some shades of difference between them. Mortification is the most general term; gangrene, perhaps, is more particularly employed to denote external superficial mortification; and the word sphacelus is employed in cases of an entire limb, or a considerable portion of a limb,

mortifying. We use the words *slough* and *sloughing* as synonymous with those that I have just mentioned; but these terms are English words, derived, according to Horne Tooke, from the Anglo-Saxon. Sloughing is equivalent to perishing, and the term slough denotes that portion of the body which has perished. Now you recollect that the word slough, in common language, is applied to the covering of the snake, which separates annually from the surface of its body; in short, slough denotes the portion that has perished, and is thrown off from the body.

Mortification consists in a cessation of the living action of the part; or more particularly, we may say, in a cessation of circulation in the part. The consequence of this is, that the part loses its heat, its sensibility, its power of motion, and its natural color; it becomes blue or livid, or brown, or blackish, or assumes various combinations of all these different tints.

When this cessation of vitality has taken place, the part then undergoes spontaneous or chemical change;—the textures that compose it become softened. Very commonly the part at the time it mortifies contains an abundance of fluids; all its vessels are replete with them. Now these fluids, as well as the solid parts which contain them, undergo a chemical change, and the textures of the body become reduced to a pulpy mass, that is exceedingly offensive. Gas is disengaged from the parts thus changed. Under other circumstances the part undergoes a change the very reverse of this, for it becomes dry, and shrinks or shrivels up; and instead of putrifying, it passes into a state in which you may preserve it—you may hang it up in the air, and it will keep in this state for years. Now these are two very different changes, both of which are called mortification, but the difference between them cannot escape the notice of the most superficial observer. Hence, from the most ancient times, you find a distinction between the moist or humid gangrene (*gangrena humida*), and the dry gangrene (*gan-*

* The observations made by Mr. Lawrence at the commencement of Lecture XIII. on Hectic Fever, were placed at the end of the one which preceded (see our last No.) as rendering the subject of Suppuration more complete; while the first part of the account of Mortification, though delivered at the end of the former lecture, is placed at the commencement of the present, so as to render the narrative more continuous.—R. G.

grena sicca). These differences are nearly equivalent to the distinction into acute and chronic gangrene, because the humid or moist gangrene is that which takes place from active inflammation, leaving the part with all its vessels filled with fluids; while the dry gangrene takes place in a slow and almost imperceptible way. All parts of the body are liable to mortification; I believe we may say *all*, but all are not *equally* liable. The cellular membrane is said to be the most prone to mortification. The skin may, perhaps, come next in order, but is much less liable to it than the cellular membrane. The blood-vessels resist mortification longer than any other texture; and thus, in cases of extensive sloughing, you often find the trunks of large vessels remain unchanged when all the surrounding tissues have perished.

This mention of the resistance of the blood-vessels to the process of mortification leads me to observe that the blood which is contained in those vessels becomes coagulated in the neighbourhood of the mortified part, and even to some distance beyond it; so that when the dead part comes to be separated from the living, there is no loss of blood in consequence of the opening of such vessels. This process of coagulation in the case where mortification affects the lower portion of a limb, will extend in the main artery very considerably above the part to which the mortification seems to extend externally. This is sometimes witnessed in cases of amputation of the thigh; where, though the mortification has not extended above the knee, the femoral artery has nevertheless been completely plugged up—filled with coagulated blood, so as not to require a ligature.

The part which has undergone mortification is separated from the sound part of the body by a process which will afterwards be described. I may only mention here that there is a considerable difference in point of the time that is occupied in this separation in particular cases. You may sometimes find a mortified part separated in a few days; and in other instances the separation will occupy many weeks, or even months: and a similar difference occurs in respect to the time that elapses before the changes that constitute a state of mortification are complete. There is a considerable difference, too, in the constitutional symptoms that are seen in different instances of mortification. In a case of slight mortification of the superficial parts, there are often no constitutional symptoms at all. When mortification is the result of high inflammatory action, there is generally a remission of symptoms on this taking place;—at the time that mortification occurs, the high febrile disturbance is greatly diminished; but if the mortification be not very considerable, the local inflammation may go

on nearly in the same degree, and there will then be little difference observed in the constitutional symptoms. Where any considerable part of the body has perished, we generally find that constitutional symptoms, of a very marked kind, attend the process. You will have occasion to observe, what we pointed out in speaking of sympathetic inflammation, the conformity between the character of the constitutional disturbance and that of the local disease; for where a part of the body perishes in this way you find general symptoms of debility are present—symptoms approaching very much to typhoid. The pulse is very feeble, intermittent, and irregular; the body is covered with a clammy sweat;—there is a complete loss of muscular power, sometimes even with syncope; hiccup takes place; the alimentary canal becomes distended with gas, approaching to the tympanitic state. In fact, all the circumstances denote the lowest degree of depression in the powers of the system generally*.

The causes of mortification are very various: hence the mode of its occurrence, the state of the affected parts, and the whole progress, are very different in different instances. Under the head of causes of mortification, we include a great variety of agencies which are capable either of suspending the circulation in a part, or of producing such violent disorder in the circulation as leads to its suspension; the nature of the affection being essentially a cessation of vital movement in the part. Now, among these causes, there are some which will always produce that effect whenever they are applied to the body; there are others that only produce that effect when applied under certain circumstances—that is, when they are applied to individuals in a particular state of health, or possessing a particular kind of constitution. Thus certain unhealthy states of the constitution, which are called in common language, and not very inappropriately, *bad habits of body*, are the most powerful predisposing causes of mortification. There are some states of the general health in an individual which will lead to the occurrence of mortification on the application of an immediate exciting cause. There are also certain states of particular parts of the body which are capable of producing a predisposition to mortification, and in which this will occur very easily. For example: it sometimes happens that the arteries of a limb become considerably changed in structure, and are converted into bony tubes—they become ossified; and when this extends from the trunk into the minuter ramifications, you cannot wonder that the circulation in the

* Up to this point, these remarks were made at the conclusion of the preceding lecture.

capillary vessels should be disturbed in such a way as to lead to mortification.

The division, then, of predisposing and direct or immediate exciting causes, is as important in mortification, as in the consideration of inflammation and other parts of pathology. Among the causes of mortification, we may enumerate the application of intense cold to the body, the infliction of any serious local injury, the direct interruption of the supply of blood to the part by pressure, or by ligature of the main artery of a limb. In the same way, certain diseases of the heart, particularly those which produce a contraction of the orifice of the aorta, are capable of leading to mortification. Two or three winters ago, there was a patient in the hospital who had a disease of this kind, and mortification of the toes came on in both feet in consequence of it. I had very little doubt that it was from disease of the valves of the aorta, so as to interrupt the passage of the blood into that vessel; but the body was removed so speedily after death, that I had no opportunity of examining.

Local pressure on a part in which there are veins and arteries both, such as the stricture in strangulated hernia, or general pressure on a whole limb, particularly when this is in a state of inflammation, leads to mortification. Now it sometimes happens, after serious injury of a limb, that a bandage is applied to it, and the limb which has received such injury swells; and thus the bandage, which was applied with only a proper degree of tightness at the time, forms an excessively firm ligature over the whole of the limb, and in this way it has happened that even the application of a bandage by a surgeon has led to mortification of a limb, and to death. The pressure on a part of the body by a particular position, long kept up—for instance, when the patient has been kept lying on the back, or hip, for a long time, by illness, the portion of the skin on which he rests will mortify in consequence of that circumstance. Violent inflammation results, which first excites the circulation and then leads to its suspension. It appears as if, under violent inflammation, the disorder in the circulation was carried sometimes to a pitch which the part is not capable of sustaining; so that the blood stagnates, and, in fact, the part perishes. Generally speaking, a high degree of inflammation is necessary to produce this effect; but sometimes mortification occurs with a degree of inflammation that does not appear to us to be of the very highest kind; and, in fact, we must consider, in relation to this mode of termination, the state both of the part itself and of the system in which the inflammation takes place. When a part has been in a weak state, a comparatively slight degree of inflammation will

be sufficient to produce mortification; and when a part is frost-bitten, the inflammation, although not violent, leads at once to mortification. In the case of an anasarctous limb, when a blister has been applied to it, or when, by scarification, we let out the fluid with which it is distended, it is by no means uncommon for mortification to be produced by these comparatively trivial injuries, and here you must explain mortification not so much by the amount of inflammation produced as by a comparison of the action with the degree of power in the part. I have already mentioned to you the fact of a change in the state of the arteries in which they become ossified: now certain other internal causes, the nature and operation of which are unknown to us, are also capable of producing mortification. Thus, feeding on ergot of rye, or that particular state in which that affection takes place which the French call *ergoté*, and which we call spur-dried,—in some way that we cannot explain, predisposes the individual to mortification; so that, in those countries where rye is the ordinary article of food in bad seasons, numerous cases of mortification have occurred obviously owing to this cause.

Mortification, too, sometimes happens in consequence of external causes, the nature and operation of which are equally unknown to us. Thus the contact of the skin with an animal substance, in certain states of decomposition, will produce a gangrenous affection which is called malignant pustule.

Now the various causes of mortification that I have enumerated, might be divided under two heads—*internal* and *external*. To the *internal*, those which are most important, belong—viz those particularly unhealthy states of the constitution which I have mentioned as giving a predisposition to mortification. The prognosis in mortification is generally serious. There are some mortifications, indeed, which are small in extent, which are derived simply from external causes, and which are unattended with any kind of danger. Thus a person may have mortification of the skin covering the tibia, from a blow upon it, and this is scarcely a dangerous occurrence. The skin covering an aneurism becomes thin when this approaches the surface, and it frequently mortifies; and the same may occur in the skin of an abscess when it points. These are examples of slight mortification from causes that merely act on a small part of the body, and which are attended with no kind of danger: but in other instances, and especially those in which mortification is referable to internal causes, and in which we cannot explain the circumstances in the way above alluded to, the prognosis is always very serious. The extent of the change which mortification produces—the depth to which it goes—the

importance of the organ which it affects—the state of the constitution of the individual in whom it occurs, are all points that must be attentively considered, before you venture to pronounce an opinion as to the probable result of any case.

In an affection, of which the nature and cause are so dissimilar, in different instances, you will naturally conclude that no one mode of treatment can be appropriate to all cases. Heretofore, attention has been chiefly given to the circumstance of the loss of vitality in the part affected, and the consequences which would attend the loss of vitality in those parts to which mortification seemed to be extending. Hence the idea has arisen, that means should be taken to stimulate and support the vital power in the part so circumstanced; and thus the general rule in mortification has been to employ stimulants—local and general—external and internal—to give bark, tonics, and cordials, as well as full and nutritious diet. This is by no means right as a *general* plan of treatment for mortification. Undoubtedly, in *particular* instances, it is requisite to employ remedies of this character, but we can by no means say that such practice would be right *generally*.

Again, some have asserted that mortification is always preceded by inflammation, and they have regarded in the affection principally the circumstance of its origin, and the inflammatory character of the primary action. It is, perhaps, rather doubtful whether this notion can be completely verified in all cases. It is somewhat doubtful whether distinct signs of inflammation do always precede mortification; at all events, we should certainly go very far wide of the mark if we attempted to treat all cases of mortification by antiphlogistic means. You can easily suppose that in that kind of extreme exhaustion of the vital powers which characterizes mortification, it would be actual madness to employ antiphlogistic treatment.

The general indications of treatment in mortification are *first* to prevent its occurrence; *secondly*, to arrest its progress; *thirdly*, to facilitate the separation of the dead parts from the living, and, under favorable circumstances, it is proper to accomplish that separation by surgical operation. These are the general indications which the treatment of mortification presents.

In considering the first, we must bear in mind, *the nature of the particular cause of mortification*. Antiphlogistic treatment will prevent the occurrence of mortification, when it is likely to come on in consequence of acute inflammation; but when a part is likely to go into mortification from exposure to cold, a judicious mode of restoring the temperature of the part will be most likely to obviate its occurrence; and so in each individual instance, the treatment calculated to prevent

the occurrence, must be adopted, from a consideration of the cause which produces the mortification, and of the particular nature of the affection in the part.

It is an important consideration what are the means by which the second indication can be employed, *that of preventing the progress of the affection*. Heretofore mortification has been regarded too much in the light of putrefaction, decomposition, and decay of the part affected. In the attempt to fall on those means by which its progress might be arrested, investigations have been made to discover those substances which would prevent the progress of putrefaction in dead animal matter; and it has been argued that the same means which would prevent this, would equally arrest the progress of mortification in a living body. Hence the class of what is called *antiseptics*, that is, of substances calculated to prevent putrefaction, has been principally relied upon in the external treatment of mortification; alcohol, camphor, turpentine, and bark, are agents that we well know are capable of preserving for a length of time dead animal matter, and of preventing those changes that would otherwise take place. Now, however, you are aware that the change which occurs in mortification is not to be considered as identified with putrefaction; and although those substances that I have mentioned would prevent putrefaction in a dead body, it by no means follows that they would prevent a living part, that was in a state of serious disorder, from going into mortification. With reference to arresting the progress of mortification, we want to discover, not what substance would preserve the part for a length of time when dead, but what will prevent the part while still living from losing its vitality and passing into a state of mortification. Now if you consider, that in a number of instances the living parts which are attacked by mortification, are in a state of high inflammatory action, you will immediately perceive that alcohol, turpentine, camphor, and such substances, cannot be well calculated to prevent the occurrence of mortification; and, indeed, we may dismiss altogether from the catalogue of local means the substances called antiseptic, which are so much recommended by old writers in the treatment of mortification. Their practice arose from an erroneous view of the subject. There are certain substances which have the power of correcting or of destroying the factor which attends the process of mortification. Charcoal is one: and thus the application of charcoal to a part which has mortified is often advisable, with reference simply to removing the offensive and annoying smell which accompanies the process. For this purpose you usually find that charcoal, whether in cases of mortification or any other kinds of diseased action which are attended with offensive odour, is recommend-

ed. But the most powerful agents in removing these unpleasant circumstances in mortification, are the chlorides of soda and lime, which have lately been introduced for that purpose by the French, and have been proposed by them, not only as applicable to mortification, but as disinfecting agents generally—as means capable of destroying offensive effluvia—effluvia that might produce disease under particular circumstances; and I believe they may be said generally to possess that power in a complete degree. Certainly, if you apply to a part of the body which is undergoing the process of mortification, cloths steeped in a solution of chlorides of soda or lime of sufficient strength, you find the unpleasant smell will be completely removed; and if you sprinkle a little of these fluids over the bed-clothes of the patient, the apartment will be rendered perfectly sweet. Now the French have gone farther, and said that these substances are not only capable of destroying the offensive effluvia in mortification and other cases, but that they also tend to arrest the progress of mortification; that they stop the diseased action, and if they did so, they would indeed be important remedies. Mr. Alcock has introduced this subject to the notice of English readers in a publication, in which he has collected the information chiefly of the French writers; and he is of opinion that these substances possess a power of acting on the living parts threatened by mortification, so as to check the progress of the disease. In instances where I have seen them used, it has appeared to me that they are to be regarded merely as disinfecting agents; that they are capable of destroying the offensive effluvia connected with the process of mortification, but that they do not possess the power of checking the progress of mortification by their agency on the living parts to which the mortification is extending.

The internal treatment must, of course, be various, according to the condition of the general symptoms. In cases of acute inflammation you may have to employ antiphlogistic means;—but in cases where the symptoms have assumed the typhoid character, which I have already spoken of, you must employ remedies of a contrary kind; bark, stimuli, wine, brandy, and, in fact, all the means, both in diet and medicine, which are capable of supporting the strength of the patient. Under such circumstances we cannot lay down any one general rule.

I now come, then, to the third indication, *the means of favoring the separation of the dead part from the living.* When the mortification is extending, we cannot accurately trace the boundary between the dead and the living parts; they seem to be confounded together; and at all events near the edge of what we conceive to be the dead part, we find that the living part, if it be not actually black or brown, is perhaps of a dark livid tint, and

seems just passing into those colours, and the surrounding living parts are perhaps vesicated. It is in this way that the mortification is carried on, affecting fresh parts in succession. But when the mortification has stopped, we then see a defined edge to the dead part, and we observe that the living portion, immediately adjoining the edge, assumes a brighter red colour; in fact, the boundary of mortification manifestly shews the occurrence of inflammation, and then the absorbents begin to perform the act of separation, and the division between them gradually deepens. Thus the mortified part is separated.

Now, in order to favor by local application the performance of this process, in general all we can do is to keep the part at rest and covered by a soft warm poultice: a poultice of bread or linseed meal answers the purpose extremely well. Sometimes it appears that the natural process by which the separation is effected does not go on so favorably as it ought to do, that the living parts which adjoin the dead are languid, that they require some stimulation; and in fact that the separation goes on better under the employment of local stimuli. An old application of this kind consisted in an admixture of yeast, or the grounds of stale beer, with bread or linseed powdered to make a poultice. This is called a yeast poultice, and this may be made rather more stimulating, if it be necessary, by an admixture of oatmeal instead of linseed. Yeast is employed in making the poultice instead of water. The dilute nitric acid may be beneficially employed to hasten the extension of the boundary between the dead and the living parts; a solution, containing four, six, and from that to ten drops to the ounce of distilled water, may be used, and lint dipped in it applied to the part. A little yellow basilicon at times will do much to assist the object in view. Balsam of Peru is another kind of application employed on such occasions, and if it does not stimulate the parts much, it at least tends considerably to correct the factor connected with the process of mortification. In some instances, powdered camphor is advantageously strewed on the surface of the parts in which the process of mortification is going on. It is rather a powerful stimulus, and should only be employed where the parts are particularly languid. These are the means by which we can favor, in the way of local application, the separation of a part which has mortified from the living portion of the limb.

Then as to the question of removing the dead part in case a limb is affected by mortification. The general rule has been not to perform amputation until the boundary between the mortified and the living part is decidedly established. No doubt this is a very wise rule. In instances where an entire limb is

the seat of mortification, it will generally be found that the state of the constitution—the health at the time—has had much to do with the occurrence, and with the progress of the affection, and therefore, until the mortification is decidedly arrested, you may suppose that the same disposition to mortify which has given rise to the first occurrence of the complaint, still exists, and consequently, if you amputate a limb under these circumstances, the wound made by the operation will take on the same condition, viz. mortification. Hence has been grounded the rule which has been laid down, not to think of performing amputation in a case of mortification until the boundary is completely and decidedly established. When the process of mortification has thus come to a natural crisis, you may suppose that a more healthy condition of the frame has occurred, and you may expect that the wound made in amputation will go through the process required for the cure in a favorable way. I have seen an instance in which the toe, for example, has been the seat of mortification, where the condition of the limb has appeared quite favorable, free from any thing like disease; where the patient has seemed in a tolerably good healthy state, and where from the very slow progress of the affection, it has been supposed that the disposition to mortify was worn out: in instances of that kind where amputation has been performed, although the boundary was not clearly established, frequently—I believe I may say generally—the process of mortification has come on in the stump, and the operation has terminated without any advantage. So that in all instances where mortification arises from or is kept up by *internal* causes—by an unsound state of the constitution, you must not make that the time for performing the operation of amputation. But in certain cases of mortification arising from *external* causes, this rule may be relaxed.

Having offered to you these general observations relating to mortification, I have a few words to say respecting some particular points.

Mortification may be produced by *cold*. Cold, whether it be applied to the body *generally*, or to any *particular* part, has in a very decided manner the effect of diminishing vital action. Thus, in countries that are very cold, where persons frequently have certain parts of the body exposed to a temperature below the freezing point, it is by no means uncommon to have such parts chilled, reduced in temperature, and in fact actually frozen. As this is a common occurrence in those countries, experience has taught their inhabitants what is the proper mode of proceeding when a part of the body is thus frost-bitten, in order to prevent it going into a state of mortification. Now it has been found, that if a part of the body thus

chilled is suddenly brought to the fire, it loses its vitality, and invariably mortifies; and the only mode to prevent this, is to raise the temperature of the chilled part *gradually*, by applying to it, in the first instance, snow or iced water, the temperature of which is only a little above that of the part itself. The state of freezing is thus removed; and then, though the vital movement had ceased for a time, although the circulation had actually been stopped, the movement and the circulation will return again, and the part recover without going to mortification. This is the mode of treatment in frost-bite.

In respect to the mortification that arises from *local injury* affecting any limited portions, there has but little been said in any book on the mode of treatment—the occurrence is unimportant, and no rules have been laid down.

The mortification which arises from *serious local injury*, and which affects an *entire* limb, is one of very great consequence. This comes on in consequence of extensive bruises or lacerations—in consequence of very severe gun-shot wounds—in consequence of bad fractures; these last sometimes produce a complication of displacements, with extensive lacerations of the soft parts, perhaps even the injury of some of the principal vessels and nerves. Under such circumstances, mortification will come on suddenly in an entire limb. The limb swells, and loses its natural colour; it becomes livid, black, and blue, and loses its temperature. A thin effusion is found disseminated through its textures, the cuticle separates, vesicles occur filled with fluid, and these changes in a short time will extend in the whole of the limb, and quickly reach the trunk of the body. This occasions that which is called *traumatic gangrene*—that is, gangrene consequent on a wound or violent local injury.

You may judge of the rapidity of the affection in this case by what Larrey mentions, who has given several instances that he had observed, principally in consequence of gun-shot wounds. He says that in some of these he has seen the process of mortification reach the trunk in six hours. If such a case be left to itself, death is inevitable. The only question is, whether under these circumstances, provided we see the case sufficiently early, we may attempt to save the patient by amputation; as for waiting for the boundary, here it is out of the question—to do so is to lose the patient. This, therefore, is a case in which it becomes a question whether we ought to adhere to the general rule that I previously laid down. Now here we must consider not merely the state of mortification in the limb, but also the condition of the patient's constitution in whom it occurs. There are certain individuals of a bad con-

stitution in whom traumatic gangrene may take place, and in whom the mere state of the system alone, independently of the serious local injury, would be a sufficient reason against performing amputation. I mentioned in a former lecture having seen one of Whitbread's draymen brought to this hospital, in whom, from a small graze of the leg, in about 48 hours mortification had extended to the whole of the lower extremity. In an individual in whom so serious an effect could be produced from so slight a cause, amputation would be out of the question. About three or four weeks since, I was sent for to see a gentleman without being aware of the nature of the case that I should have to witness, and on entering the room I was much surprised with the look of the patient. He began to speak, but he appeared as though he could hardly exercise the muscles of articulation. I put my fingers on his pulse, and found it sinking. The hand was cold, and I then found he had an affection of the other arm, which I was desired to look at, and when it was opened, to my great astonishment, I found the fore-arm mortified. It was cold, livid, and discoloured, and the process of mortification extending up the arm. On inquiring into what had occurred in this case, I found the gentleman was not aware of any other cause for this state of the limb except that some one, who passed him in the street, had struck him upon the elbow a few days before. The part became uneasy; it swelled, and he applied to a medical man, who sent his assistant, and he applied some leeches for him. But the medical gentleman himself, by whose desire I was requested to see the patient, had not seen him until less than 48 hours of the time of my seeing him, so that in that short period this traumatic gangrene had extended, as I have mentioned, from so trifling a cause. It is obvious, that under such circumstances, it would have been of no use at all to have thought of amputating the limb. In the feeble state to which this person was reduced, the mere operation would have been sufficient to extinguish life, and in fact the patient died within 24 hours of my seeing him.

A number of years ago an Irishman was brought to this hospital, who had fallen from a scaffold three stories high. He did not fall direct to the ground, but from the third story to the second, from the second to the first, and from thence to the ground, by which he received a severe injury of the wrist. He was under the care of Sir Ludford Harvey. I came to the hospital one morning, and was requested to see this patient—it was about three or four days after his admission. On the preceding night, at bed-time, the dresser under whose care he was had left him well; for he had seen him late, and he ascertained that he was then well. In the morning the patient told the

nurse that he had been in a dreadful state of pain all night; she came to the dresser, and at his request I went to see him. I found the fore-arm, from the wrist up to the elbow, enveloped by a bandage, which was not tighter than seemed to have been proper; but in consequence of the limb swelling, it had become too tight. On feeling the hand it was quite dead. On taking off the bandage, the fore-arm was livid and cold up to the elbow; the fore-arm in the lower part was not, perhaps, actually dead, but in a state immediately implying mortification. The discoloration of the skin reached as high as the shoulder, and this state of the limb had come on in twelve, or at the utmost fifteen hours. Now this was a stout young Irishman, of excellent constitution, and therefore a fit subject to try to save by operation; and although I could not see that the integument was perfect in color where it was necessary to amputate, yet I thought I would give him a chance. I removed the arm at the shoulder joint, and in fact the cellular membrane was discolored, and something of a yellow fluid was infiltrated in the part where I made the incision. The case succeeded perfectly, and the patient recovered.

I have seen one or two other instances in which amputation has been successfully performed in traumatic gangrene before mortification had stopped, and consequently before the line of demarcation had taken place between the dead and the living parts. Several such cases are recorded by Larrey, in his "Memoirs of Military Surgery," and I believe of late years there has been an accession of evidence on the same point; so that I have no hesitation in saying that in the case of a patient of a healthy constitution where gangrene arises, as in such cases from external causes simply, you must disregard the general rule that I before mentioned respecting the performance of amputation. The removal of the limb in many cases will be the means of saving the patient's life, which otherwise must be inevitably lost, from the serious nature of the affection, and the rapid way in which it extends over the limb.

In elderly persons mortification occasionally takes place—more especially in consequence of the changed state of the arteries of the limb, which become ossified; and this particular form has been called *gangrena similis*, or the gangrene of old age. A portion of the end of one of the toes, or some part of the foot, becomes livid, the cuticle is raised by a sanious fluid, and vesication takes place. The patient experiences perhaps little or no pain, and when you open the vesicles of the cuticle, and let out the fluid, you see that the skin which is exposed has lost its vitality.

Now the part thus mortified readily

shrinks and shrivels—it goes into a state of dry gangrene. The part thus mortified may be separated from the limb, and leave it in a healthy state; but then generally mortification occurs in some other part, and from the slight point at which it first begins, it probably extends and creeps along the foot, so that generally when you have an occurrence of this kind, you find the patient dies from it, although the mortification in the first instance may appear to be very slight in extent. It takes place with so slight a disturbance in the part, and so little constitutional affection, that at first you are hardly aware of the dangerous nature of the disease. Sometimes this gangrene of the toes of old persons is attended with very considerable pain, and it is this form of the affection in which Mr. Pott warmly recommends the administration of opium in large doses, on account of the pain with which the process is attended. You cannot do better than keep the part at rest, and cover it with a soft poultice, assisting the process by some means of a local kind.

I have mentioned that generally these cases terminate fatally. When you once see a limb vesicate, it is an evidence of the deranged constitution of the individual in whom it occurs; and however favorable the circumstances may appear for a time, you seldom find that the patient escapes. Some time ago I saw a gentleman in whom this affection had taken place on the under surface of the last phalanx of the great toe: he was between 50 and 60 years of age, and had been in the habit of living well, and by no means working hard; in short he was an indolent person, in a full corpulent state. He eat and drank well, and had got a red pimply face; but was surprised that any thing should be the matter with his toe. It gave him little trouble, and it was with difficulty he could be prevailed upon to keep quiet, and not to walk about. However the part mortified, and he was persuaded to go to bed. The mortified part separated, a granular surface was formed, and it appeared to be on the point of healing, when, without any apparent cause, the whole of the toe mortified up to its junction with the foot. A groove took place, and formed a separation between the living and dead parts, and the progress of the mortification was arrested. The soft parts separated, and I cut through the bone with a pair of pincers. A granulated surface appeared, and there was reason to suppose that it might heal soon. However it assumed a livid character, and a little further on a deep-seated supuration, of an unhealthy kind, with a formation of foetid pus, took place in the foot; and thus the patient was carried off.

In the course of the summer of 1828, I saw another gentleman, about the same age, and a very similar habit of body, in whom mortification took place at the side of the

heel. The dead part measured about an inch one way, and three-fourths of an inch the other. In this gentleman the process of separation took place in about two months, and he got well, and remains well to the present time. This is an instance which proves that this mortification does not invariably terminate fatally; but inasmuch as it is generally connected with an unhealthy state of the part, and inasmuch as it generally occurs in patients whose constitutions are impaired by sedentary indolent habits and full living, you will usually find that they terminate badly, although for the time the natural process of separation may take place, and the case may seem to be on the point of doing well.

I may just mention to you cursorily the occurrence of mortification from the application of animal matter in a state of decomposition, under the term *malignant pustule*. Under this name a certain state of the skin has been described by continental writers, and I fancy the case is more common with them than with us. It especially happens to butchers, and persons that have to do with hides, and it is said to take place more particularly where butchers have to slaughter animals that have died of disease.

I will only mention one case, that of a person who was employed in Leadenhall-market. He had to handle some very stinking hides that came from South America, and in doing so, one of these putrid hides swept by the side of his face. He was aware that it touched him, and that it left some nasty stuff, about one inch and a half square, under the lower eyelid. Where the surface of the skin had been touched, it first became red and swelled, and from that it became oedematous; the part that was red measured more than one inch each way, and a slough formed, which occupied not only that part of the skin, but that adjoining the cellular tissue: the part separated, and he lost a great part of the cheek; but the lower part of the eyelid was saved. That is a singular example of the deleterious kind of effect which decomposed animal substances has over the skin.

AN ESSAY

ON

ARTIFICIAL TEETH,

BY LEONARD KOECKER,

Surgeon-Dentist, Doctor in Medicine and Surgery.

(Concluded from page 178.)

On Pivoted Teeth, or the engrafting of Artificial Teeth upon the remaining Roots or Fangs.

THIS mode of inserting artificial teeth

has been adopted and sanctioned by custom from time immemorial; and although, on a superficial view, it might, from its great simplicity and natural appearance be considered as a very convenient process, it will be found on a deliberate consideration to be by no means founded on good pathological or surgical principles.

In referring, not only to those works on dental surgery, which have been written more for the interest of the authors than the promotion of science, but also to all others which treat on the mechanical part of dental surgery, which I have had an opportunity of perusing, I find that they all consider it an useful and desirable method of restoring lost teeth.

Mr. Fox, in his "Natural History and Diseases of the Human Teeth," part 2, p. 139, in referring to a tooth inserted in this manner, says, "it may continue for many years without occasioning any trouble, or requiring any repair. In this mode several teeth belonging to the same person may be replaced which cannot be discerned upon the most minute inspection;" and the view of this excellent dental surgeon may be regarded as the opinion generally entertained, not only by practical dentists, but also by the public at large.

For my own part, however, I cannot help differing from the opinion of this operation, so generally received, as I conceive it to be one which requires great restriction, and which is frequently highly objectionable, being always attended with more or less sacrifice of health, and sometimes even with fatal results, although I will not deny that it has frequently met with considerable success, and has not been followed by great inconvenience, but that such artificial teeth have been used for many years without requiring much repair. I have in my own practice frequently applied these teeth, and almost invariably with a favourable result; and have often found them in a good condition even after a period of many years.

Artificial teeth of this kind are frequently used after the crowns of teeth have been so destroyed by caries as to leave little more than the roots in the sockets, and are mechanically inserted in the following manner.

All the irregular and carious remains of the crown of the tooth are filed away close to the gum. The natural cavity,

or canal of the fang, is then prepared to receive the pivot by passing a small branch into the cavity, and drilling it into a round hole. The crown of a human tooth, or a mineral tooth, resembling the one lost, is then made to fit to the fang; a pivot, somewhat shorter than the cavity in the root, is introduced into it, and the artificial tooth inserted by means of the pivot upon the root, where it is then properly fastened.

Having given a concise description of the mechanical process of this operation, it remains for me also to place the same before the reader in a pathological and chirurgical view, and to point out its effects upon the parts involved in the operation as well as upon the constitution. In my "Principles of Dental Surgery, &c." p. 254, I have more extensively treated of the morbid effects of dead teeth and roots, to which I beg to refer the reader; and I shall here only remark, that by the insertion of artificial teeth in the above manner all the morbid effects of such roots must be augmented and aggravated.

By the insertion of the pivot in the canal of the root, the natural curative process, or the decomposition and absorption of the fang, is prevented or retarded; while on the other hand, the most convenient outlet for a constant and regular discharge of the matter, which is always produced by the carious root in the surrounding soft parts through its canal, is obstructed. The matter thus confined penetrates through the sockets and gums, and forms gum-boils, or small fistulous abscesses in the neighbourhood of the root, producing inflammation of the gums, and caries of the sockets, much more frequently than when these structures are left under the exclusive influence of disease.

In many instances, and more especially if only one or two teeth have been inserted in this manner, these morbid symptoms remain in a chronic state for many years, and the patient experiences apparently very little or no inconvenience. In others, even after the insertion of a single tooth, they become more acute and extensive; and painful swellings of the face and jaws, sometimes accompanied with great disturbance of the system, are consequences of frequent occurrence. If a greater number of teeth have been inserted with pivots, the symptoms are generally aggravated; the whole mouth becomes more or less

affected; the gums become spongy and painful; the sockets morbidly softened; the periosteum becomes thickened and relaxed; the jaws are affected with chronic pains; and these local affections are followed by a train of general symptoms of various descriptions. These symptoms are of most frequent occurrence in weak and irritable constitutions; and it is impossible to say to what extent the mischief may proceed if the fangs are not removed, which, although it almost invariably produces a perfect cure of the local diseases, is too often delayed till the patient has experienced all the evil effects above stated.

Several cases have been related strikingly illustrative of the danger connected with the insertion of these teeth, in my work on "Dental Surgery." The first of these is that of a lady in Germany, who suffered a most deplorable death in consequence of the application of one tooth of this kind; and the other that of an American lady, whose face was greatly disfigured by the insertion of one incisor tooth. And case No. 1 of this Essay, as well as the subsequent cases, Nos. 3 and 4, selected from a considerable number which I have had an opportunity of observing during my practice, are equally illustrative of the pernicious effects following the injudicious insertion of pivoted teeth.

CASE III.—Mrs. —, of Philadelphia, about 40 years of age, under the medical care of Dr. Chapman for a train of those nervous, rheumatic, and dyspeptic complaints which generally baffle all medical skill, was requested by that eminent physician to consult me respecting her teeth in 1820.

By examination I found that she had the four upper incisors, and two cuspidati, restored by artificial teeth ingrafted on their roots. Finding the artificial teeth to be loose, and observing several gum-boils about the roots to which they were attached, I became suspicious of the cause; and on a careful investigation discovered that all the sockets belonging to the six roots in which the pivots were introduced, were perfectly carious; entirely detached from the jaw; and, together with the artificial teeth and dead roots, were only held in their places by the gums. Having lost the greater part of her molares, the lady could not prevent, during speaking and mastication, the contact of the artificial teeth;

and the constant motion thereby produced kept up a permanent irritation, which could not fail, in combination with the very diseased state of the mouth, to produce the most distressing local and general symptoms. I of course advised the immediate removal of these roots; but, unfortunately, the lady was in that nervous and irritable state of mind and body that all the combined persuasion of her physician and myself could not induce her to allow me to remove them; and she continued the use of her artificial teeth for some years longer, submitting, at the same time, to the continuance of all her sufferings.

CASE IV.—Miss —, about 28 years of age, although originally of a very strong constitution, was in so precarious a state of health that she had not left her house for two years: great debility, frequently accompanied with fever, and all those painful and distressing symptoms which generally attend the highest degree of nervous irritability, had gradually so debilitated her constitution, that her medical attendants had declared her to be in a consumption, and the patient, as well as her friends, had for some time despaired of any permanent recovery, but were endeavouring to reconcile themselves to the painful result which they considered to be at no great distance.

To this view, however, one of her physicians would not positively agree, but considered that her sufferings might be principally founded on dyspepsia, and a long train of those symptomatic affections concomitant with that disease. This gentleman being a staunch adherent of my theory of the great influence of diseased teeth upon the constitution, he suspected that her general health might be suffering from the diseased state of her mouth, and that by proper treatment of these local diseases, great progress would be made towards her recovery, and therefore requested that I should be consulted. The lady had suffered principally from the irritation produced by the violent and unskilful insertion of seven artificial teeth with pivots upon the roots of the four upper incisors, two cuspid, and one bicuspid tooth. I proposed the removal of all the fangs on which the artificial teeth were fastened, as well as of a few more diseased teeth and stumps which had also been very improperly permitted to remain.

January 20th, 1828.—The lady gladly acceded to my proposition, and nine carious teeth and roots were immediately removed.

February 29th.—Visiting the lady again at her own house, I found her general health greatly improved, and her mouth in a sufficiently healthy state for the scaling of her remaining teeth.

March 12th.—The health of the patient had so much improved that she was able to ride a considerable distance to town, and submit to a fatiguing operation for the preservation of her remaining teeth.

April 12th.—Some of her teeth were rendered sound by filing and stopping some carious places with gold.

26th.—The patient had almost completely recovered her health; one tooth was rendered sound by stopping a carious cavity with gold; her whole mouth was now in a perfectly healthy state; and the impression for a set of artificial teeth was taken at the same time.

May 15th.—The lady was provided with a whole set of artificial teeth, which restored her powers of mastication and her original appearance, and she has hitherto uninterruptedly enjoyed good general health.

On the Principles for the Insertion of Pivoted Teeth.

From the above statement and facts it seems to be sufficiently evident, that if the application and use of such pivoted artificial teeth is not always accompanied with real inconvenience and danger, but frequently even with considerable success, that this success is at least very uncertain, and that, moreover, in some instances, their injurious tendency is very great, and highly destructive to health, and even life. It would, therefore, be better to abandon the operation entirely if it were possible; but such are its mechanical advantages and its immediate apparent good effects, that it would be most difficult in many instances to dissuade both the profession and the public from the adoption of an operation which has been so long sanctioned by custom; while its ultimate and injurious effects have remained unobserved, and have been almost invariably ascribed to erroneous causes; I shall, therefore, content myself with attempting the amelioration of a treatment, the perfect removal of which is not attainable; and with this hope. I

shall now state those principles which I have adopted for the insertion of this kind of artificial teeth during my own practice, and by which I have obviated its injurious consequences.

In the choice of this operation, we should always be mindful of the fact, that although health is often strong, and nature often kind enough to bear abuses, that there is also a certain degree of this endurance which cannot be overstepped without producing dangerous consequences.

The indications for pivoted teeth, or rather the circumstances which may be deemed as admitting of their insertion, as well as the indications for their rejection, should always be the objects of deliberate consideration, previously to their application.

It should always be viewed as a very improper practice to apply these teeth indiscriminately; and, in order to proceed with safety, the following questions should receive the most deliberate attention before the adoption of this treatment.

1. Which of the human teeth are, and which are not, properly calculated, from their situation and the formation of their roots, to receive artificial pivoted teeth?

2. To what extent may this treatment be judiciously carried, and how many teeth may be inserted with safety in the same mouth?

3. Under what circumstances the application of such teeth may be admitted, and under what it should be rejected?

In reply to these questions, I must give it as my decided opinion, first, that neither the situation nor the form of any of the teeth of the under-jaw, nor any of the molar teeth of the upper-jaw, warrant the insertion of this kind of artificial teeth; and that I have therefore made it an invariable rule to apply them exclusively in those cases in which they were properly indicated for the restoration of the upper incisor and canine teeth. Secondly, that having very frequently seen considerable injury and danger accompany and follow this operation, in those instances in which a considerable number of pivoted teeth had been inserted in the same mouth, I have made it a constant principle not to exceed the use of three teeth of this kind for the same individual; and have always advised the extraction of the roots,

and the insertion of other artificial teeth, where any number exceeding the above was requisite. Thirdly, that I consider it particularly necessary to take the state of the health generally, as well as of the mouth, into consideration, previously to the application of such teeth. Delicate, irritable, nervous, and inflammatory constitutions, I have always deemed unfit for this operation; as well as those persons in whom the teeth and gums were much diseased.

In preparing the root for the reception of the pivot, every unnecessary irritation should be avoided, and no violent means should be used to remove the remaining irregularities from the root by means of pincers, but they should be removed with a half-round file, of a size well calculated to give the fang the proper form, and the cut of which is neither too fine nor too coarse. The natural cavity should be carefully and gradually enlarged with broaches of different sizes, and of such forms as to render it, if possible, equally wide throughout.

In the preparation of the artificial tooth, particular care should be taken to make it fit exactly to the root, and to give it such a form and direction as to prevent every pressure upon the natural teeth on both sides, as well as any contact, and more especially any striking of the opposite teeth upon the artificial ones.

The best mode of fastening artificial pivoted teeth, is that which produces the least irritation; and particular attention to this part of the operation is of great importance.

To attain this, inflammation or swelling in the gums and sockets belonging to the fangs should be prevented as much as possible: and with this view, I have always endeavoured to make the cavity of the roots an outlet for the matter, as well as the receiver for the pivots of the artificial teeth, instead of obstructing the natural mode of its discharge; a point which will be best obtained by a particular attention to the following rules, which I have adopted for many years.

1. After a careful preparation of the extremity of the fangs and the cavities for the reception of the pivots, as well as a perfect adaptation of the artificial teeth, with a view to allow the roots to recover from the unavoidable irritation produced by the filing and drilling, I

have preferred delaying the insertion of the artificial teeth for two or three days; and to excite the discharge through the roots, I have requested the patient to keep a small lock of cotton in the cavity, which generally produced the desired effect. Secondly, I have made it an invariable principle to insert the tooth in such a manner that the patient should be capable, after receiving the necessary instruction, to remove and replace it at pleasure. For this purpose, I have found it best and most effectual to wind a little cotton round the pivot, which should be filed somewhat rough, previous to its insertion into the fang. Thirdly, the artificial tooth should be inserted without any violence, and only with sufficient firmness to prevent it from moving, and should be taken out every fortnight by the patient, in order to clean the cavity of the roots and the artificial teeth, and to change the cotton; which having been carefully done, the artificial teeth should be immediately replaced.

Should, however, the operation be followed by any inflammation or swelling of the gums, the patient should be directed to remove the artificial teeth immediately, and to excite the discharge of any matter that may have been formed through the cavity of the roots, by keeping that canal perfectly clean, and by frequently washing the whole mouth with a mixture of one part of tincture of myrrh and three or four parts of warm water; nor should the artificial teeth be replaced until the gums and sockets have perfectly recovered from the inflammation.

The use of pivoted artificial teeth should not be persisted in for too long a time; but when the roots which receive them become loose, when the gums become considerably inflamed and swelled, and when their dark and morbid appearance evinces a carious state of the sockets, they should be immediately extracted; and after a perfect restoration of health, artificial teeth, fastened with springs, such as have been already described, should be used in their stead.

By a strict adherence to the above principles, I have always succeeded in preventing every injurious effect in my own practice; and I have no hesitation in asserting, that in all cases which have been followed by very injurious and fatal consequences, such as have been

tated in a former part of this essay, the result can only be ascribed to the culpable omission of proper surgical principles, or by the use of some positively violent and destructive modes of treatment.

Such injudicious methods, I regret to state, are not so uncommon as their absurdity and impropriety might induce us to believe; and I beg to name only a few of the most injurious kind—namely, the use of a bow and drill, or gimblet, for the preparation of the hole in the root to receive the pivot; a practice which, from the violent and rapid manner in which this apparatus cuts into the root, must inevitably produce great pain and inflammation. These are, however, the least injurious effects resulting from such injudicious proceedings; and I have not unfrequently found, after the extraction of such fangs which had produced extensive inflammation and abscess, that the drill had passed through the lateral part of the fang, and penetrated the bony structure of the socket; in other cases, that it had perforated the whole of the root, and passed into the cavity of the jaw; and sometimes I have found the root split into two pieces. Another mode, more culpable, and yet more injurious, is that of inserting the pivot with great force, and even by making use of a hammer to fasten the artificial tooth.

The materials for pivoted teeth are natural human teeth, and those of a mineral or terro-metallic composition. Some dentists apply the sea-horse and sea-cow teeth; but these materials are always more or less objectionable, as they are far less durable and less natural in their appearance than the others.

The pivots should be made only of fine gold, or platina; every other metal, such as brass, copper, silver, and even inferior gold, are highly objectionable, being more or less liable to corrode.

There is, however, a practice adopted by some dentists which is still more improper—namely, the use of pivots made of wood. These pivots, after insertion, expand considerably, from the moisture of the mouth, and, consequently, generally remain perfectly firm in the roots for several years; which misleads, not only the patient, but also the dentist, and induces them to consider the case very successful, until they are at last undeceived either by finding the root split by the great swelling of

the pivot, or nearly destroyed by the ultimate rapid decomposition of the wood in the cavity: a process which is very apt to produce very serious inflammation, not to mention the disagreeable smell which it unavoidably gives the breath.

Old Burlington-Street,
Dec. 1829.

ON THE USE AND ABUSE OF MERCURY,

And some other popular Medicines, in various Disorders, and Morbid Conditions of some of the most important Viscera.

BY ROBERT VENABLES, M.B.

St. Mary Hall, Oxford; Physician to the Chelmsford Provident Society, &c. &c. &c.

It has been supposed, by many practitioners of experience, that the exhibition of calomel, or any other active mercurials, during scarlatina, measles, and some others of the exanthemata, or during the convalescence from these disorders, is apt to induce cachexies of various descriptions, and which will infallibly manifest themselves at some period or other, sooner or later. Hence many proscribe mercury altogether in such cases; and are thus deprived, in many instances, of the sanative agency of a very useful and very powerful remedy. Although I am not prepared to admit the propriety of so exclusive an interdiction, yet I am fully satisfied that mercury, in many cases of the above description, exerts a most pernicious influence, and often establishes fatal diseases in the system. This is peculiarly the case among children of a weakly irritable constitution, and among adults also of similar temperament. Nor are these deleterious effects confined to the exanthemata alone; for I have frequently noticed them, especially among children laboring under what is commonly termed "nervous irritation."

The terms "nervous irritability" and "nervous irritation," have been regarded, and are still indeed considered, as mere cloaks for ignorance—terms expressive of no known morbid condition, nor indicative of any defined pathological fact. With them we usually associate the ideas of morbid excitability—a peculiar susceptibility; as it

were, of febricular manifestations, and irritability both of temper and constitution. If we admit such a definition as comprising the whole or even the principal phenomena, it would lead to no practical inference of any value. Indeed experience fully proves that mercury, though occasionally hurtful in such cases, is, generally speaking, one of the most effectual remedies we can employ; whether as an alterative and constitutional corrective, or as the motive agent in alimentary accumulations, and as the means of exciting the natural and healthy operations of the digestive organs. We must, therefore, look for some more decisive means of discovering those conditions of system which should deter us from the administration of mercury during the prevalence or convalescence from eruptive and other analogous disorders.

I am not aware of any obvious symptom so far characteristic of this condition as to afford even presumptive evidence of its existence. It is imagined by many, that the color of the alvine evacuations often affords satisfactory proof of the necessity of a mercurial stimulus. The color supposed to indicate this necessity is a darkish hue, comprising, however, every grade from jet black to an almost perfect white or clay colour. A very frequent appearance is that of green, and an intermixture of this colour, in various proportions, with black. The color of the stools, in such cases, is considered as affording evidence of a defective or deranged action of the liver, and requiring the mercurial influence for its correction. But in many cases, the practice not only fails, but brings the unfortunate sufferer to death's door. The stools of children are frequently, when voided, of a grass-green; and in other instances, although of a bright yellow when passed, assume the grass-green hue at an interval longer or shorter, according to circumstances. The little patient is sometimes peevish, impatient, irritable, and feverish; and in such circumstances, generally very restless and discontented. Sometimes they are dull, languid, stupid, or even comatose; and these two morbid states alternate with each other. Some, looking to the stools, denounce the liver as the seat of the disorder, while others, looking only at the cerebral symptoms, declare the disease hydrocephalus.

Should mercury happen to be administered in active doses, and the patient happily surmount its destructive influence, hydrocephalus is pronounced curable, and mercury its specific. Hence false inferences in pathology, as well as therapeutics; false, because the symptoms are inadequate and the reasoning imperfect.

There can be no doubt that discoloration, depending upon deranged function of the liver, or that a morbid condition of this viscus, will require, and may often be benefitted by, mercury; but there is a very important difference between the two cases. The pathology of the former case is as follows:—The intestinal canal is in a state of very great irritation, and its functions (particularly digestion)* are but very imperfectly performed. Hence the bile is mechanically, rather than chemically, mixed with the food; and in this way the whole is passed along the canal without being thoroughly digested. Dr. Prout has most satisfactorily proved that pure muriatic acid is secreted into the stomach. This is sometimes abundant, and, acting on the bile, produces the grass-green, which is taken as evidence of hepatic disorder. As the mucous membranes of the intestines are, under such circumstances, in a state of high irritation, mercurials (especially the more irritating preparations, as calomel, &c.) and drastic purgatives of every description, often do irreparable mischief. The consequences are cutaneous ulcerations, aphthous ulcerations of the tongue, throat, and fauces; dysenteric discharges, and gangrenous ulcers of the intestinal canal; fevers, comatose affections, insanity, permanent idiotcy, but most frequently death.

It may, perhaps, be asked, if the color be owing to the reaction of muriatic acid upon the bile, how is it that the evacuations are occasionally yellow when discharged, or why is not the reaction immediate in one case as well as another? To this, a perfectly satisfactory answer, perhaps, could not well be given. However, it may be observed that the urine is sometimes mixed with bile, and muriatic acid added will often detect it, by an instantaneous reaction. But, as Dr. Prout very accurately states, sometimes hours will elapse before the

* Under this term I include, not only the changes on the aliments, but their assimilation.

characteristic reaction appears, and occasionally it will not appear at all. The object here, however, is not to explain anomalies, but to reconcile doubts and difficulties, by an appeal to analogies and admitted facts. Suffice it to say, that I have satisfied myself of the occasional presence of free muriatic acid in the grass-green evacuations of infants. In such cases, I believe, abstractedly speaking, mercury is seldom necessary—generally prejudicial. If necessary, the mildest preparation should be given; and I know of none that agrees so well as the grey or ash-colored oxide, which, however, should always, under such circumstances, be combined with chalk, or magnesia*.

There is a certain description of pale, sallow, leuco-phlegmatic appearance, which often contra-indicates the use of mercury. This, however, is neither sufficiently definable nor sufficiently characteristic to be depended upon. But it will often lead to a suspicion of that condition, which a more minute and unequivocal mode of investigation will confirm.

I have found the urine to afford the most certain and the most decisive evidence of the existence of such disease, and of that morbid condition of system which almost invariably precludes the exhibition of mercury. If the urine contain albumen, we may generally decide against mercury. I have long considered albuminous urine as contra-indicating any active exhibition of mercury; and in my Clinical Report on Dropsies, published in 1824, I have supported this view. Indeed I have particularly noticed one case in which the urine, being albuminous, a combination of opium and mercury, prescribed for a venereal affection, appeared to me to bring on anasarca and tympany, which ultimately proved fatal. At the time I published that report, I was not so fully satisfied of the necessity of wholly proscribing mer-

cury in dropsies with coagulable urine. I then believed that a very mild alterative course was not only safe, but frequently useful, by exciting the cuticular functions and other secretions. Since the publication of that work, Dr. Bright has concluded, from numerous post-mortem examinations, that in dropsies attended with coagulable urine, the kidneys are always organically diseased. Dr. Christison has still farther confirmed this opinion; and although his dissections and cases will not warrant organic disease of these organs in the usual acceptation of the term, yet they fully prove morbid condition of structure, which cannot be considered as perfectly coinciding with, or limited to, mere inflammation.

I have been long in the habit of attending to the qualities of the urine, and I seldom neglect any opportunity of examining this fluid. Experience and observation have fully convinced me of the fact of albuminous urine being mostly connected with disease, whatever its character, of the kidneys. If the albuminous condition be fixed and obstinate, and well marked, we may generally infer organic disease of the kidney associated with disease of the bladder. This will be found true whether dropsy be present or not; and such cases mostly terminate fatally, or sink exhausted by a catarrhal discharge from the bladder, attended with ulceration, and a variety of other complicated affections of this viscus*.

* I cannot omit this opportunity of relating the following history as confirming this view, and of shewing how uncertain an opinion founded on general symptoms, compared with that founded on unerring principles, may prove. I was requested by a respectable surgeon to visit a patient of his, a coachmaker's wife, labouring under symptoms of urinary irritation, and to whom he was pleased to recommend me, as having made these disorders objects of unusual attention. On examining the urine, I found it of low specific gravity, and containing a considerable quantity of muco-albuminous matter, the former derived most probably from the bladder, the latter from the kidney. She complained of great tenderness in the right side. The soreness followed the direct course of the ureter, from the kidney to the pelvis, and no doubt depended upon inflammation, or probably ulceration, of this duct. The urine occasionally contained flakes, and sometimes small coagula of blood. The latter, however, I only observed on two occasions. The uterus was also affected, and the functions of the liver were occasionally deranged, but there was no tenderness of the hypochondrium, nor any tumefaction. I told my friend that the kidneys were diseased, and also the bladder, and that the latter was probably ulcerated, or would speedily become so. Recommended not to be imposed upon by the yellow coating of the tongue, and to avoid mer-

* The hydrarg. c. creta, and the hydrarg. c. magnesia of the pharmacopœias, are generally very inefficient preparations, and, for the most part, consist of mere mechanical mixtures of these earths with metallic quicksilver. The same objection applies to the blue pill and mercurial ointment. I therefore always direct the extemporaneous combination of the oxyd. hyd. ciner. with the earths in the requisite proportions. As a substitute for the blue pill, I prescribe the requisite quantity of the oxyde, with a grain or two of extract of henbane. These preparations are more chemical and more uniform in strength and effect.

The quantity of albuminous matter may (*cæt. par.*) be regarded as in some degree a measure of the diseased state. If the quantity be small, and its presence discoverable only by the more refined modes of chemical analysis, the disorder of the kidneys may be considered as almost mere functional derangement, and by care and attention at this period, the tendency to assume a severer form may be at all events suspended, or possibly wholly removed. But if the patient be imprudent, or be improperly treated, the kidneys and bladder will ultimately become organically deranged, and most likely a sudden termination succeed.

The serous condition of the urine may be determined by the coagulability, by heat, and by nitric acid. Frequently, however, it will be necessary to concentrate the urine by evaporation, before these re-agents will manifest the serous character of the urine. The prussiate of potass with diluted acetic acid will detect albumen not discoverable by any other means, and in some instances time is necessary to its development.

In general where there is a disposition to general dropsy, the urine is of

cury, as a poison. The patient was bled and leeches upon the right side, over the seat of the pain, and a palliative course of medicine directed. The symptoms, however, did not improve, and the patient was at last confined to bed. In consequence of some supposed inattention, either on my part or that of my colleague, the husband suddenly sent for another physician, who looking at the tongue, and laying his hand on the side, declared the disease to be seated in the liver, and that our views and opinions were all chimerical. So prejudiced was the husband, that he would not even take the trouble to inform either me or my colleague that he had placed his wife under the care of a more favoured practitioner. Accordingly, we were much surprised on making our accustomed visit the next day to learn, that we were both discarded in disgrace, as ignorant of the nature of the case, this gentleman neither having communicated nor requested any interview with us. I could not help, however, declaring on parting, that, liver affected or not, if mercury were used, the unlucky patient would not long trouble the husband, nor be an object of professional anxiety to the attendant; and that before many days elapsed, he would have unequivocal proofs of urinary disease. In about a fortnight after, the husband meeting me accidentally, told me that my prediction was partly verified, for that the urine was in such a state, and the stench so intolerable, that the house was scarcely habitable. He requested me to call and see his wife, but this I declined. I know not whether mercury had been given or not, but in about a week after, I learned that she died. Perhaps, it would have been as well to have adhered to the solution of chlorine, which I had prescribed for the bilious symptoms. I believe no morbid examination was made, which is rather singular, as the opinions of the first physician were disputed by him who succeeded.

low specific gravity, from 1.009—1.0015 the urea in small proportion, and the saline principles, as might be suspected from the low specific gravity, deficient. When serous urine is of high specific gravity, and contains urea in great excess, and abounds in saline principles, the bladder generally is more or less diseased; and often diabetes is present. It is not necessary to constitute diabetes that the urine should be in excessive quantity; on the contrary, diabetes, that is, a saccharine condition of the urine, may exist, although the quantity should not exceed, nor even amount to two pints in twenty-four hours. I have lately met with two cases of this description. I had no idea at first of the nature of the disease; but finding the specific gravity of the urine from 1.028 to 1.030, without any excess of urea, and not containing a sufficiency of saline principles to account for the density, I examined it more particularly, and discovered sugar in each specimen. In one of these cases, the bladder had been severely affected at a remote period, and the gentleman was, by the advice of a physician, on his way to London to be operated on for stone, when he was stopped by a professional friend, who directed some medicine which completely relieved him. In this case, I have had the advantage of the opinion of my friend, Dr. Prout, who has informed me that he has lately met with several cases of a similar description.

In cases of the latter description, the bladder is often tuberculated or knotted, and throws off a kind of fatty matter, which is mixed with the urine. In others, blood is voided, and then there is usually a fungous tumefaction in some part of the bladder. The symptoms often resemble those of stone, and can only be distinguished by a chemical examination of the urine. I have deposited in the museum of the Royal College of Physicians a diseased bladder, in which there was not only a fungous excrescence as above described, but a most curious cyst, formed by the mucous lining, and which would have concealed and protected a calculus from the sound. As the preparation, with the history of the case, is in the possession of the college, I consider farther allusion unnecessary.

When there is an increase of mucus or a discharge of pus from the bladder, the urine is often neutral or alkaline,

and after standing for some time, becomes spontaneously alkaline. The alkaline properties arise from the evolution of ammonia or its carbonate, formed by the reaction of the fixed alkali of the mucus upon the urea. All these conditions of the urine contraindicate the use of mercury under any form, or in any dose. When I published the "Clinical Report on Dropsies," I considered a mild or alterative course of mercury admissible, if the other symptoms indicated it. However, subsequent experience and more extensive opportunities have convinced me of my error, and I feel now fully satisfied of the injurious effects of mercury in all cases of the above description. Should hepatic derangement of any kind seem to justify a recourse to mercury, I believe a solution of chlorine will be found to answer every useful purpose, and much more safely than mercury. In dropsies of this description, I am inclined to believe even squill injurious. I know that Dr. Christison has published an able report in the *Edinburgh Medical Journal*, upon Dropsies arising from organic disease of the kidneys, and in which he questions the correctness of the opinion advanced by me, and subsequently by Dr. Bright, as to the injurious effects of mercury in dropsies attended with albuminous urine; but it appears to me as equally admitting of question, whether the cases which he has published do not confirm, rather than invalidate, the principles of caution and practice which we support.

In scarlatina, measles, and other eruptive fevers attended with coagulable urine, mercury is apt not only to excite ptyalism or salivation, but to bring on exulcerations, scrofulous tumors, and abscesses, (or at least these affections partake of the scrofulous character), and dropsies sometimes of the cavities, sometimes anasarca. Indeed anasarca so frequently supervenes the termination of scarlatina, that it might be regarded almost as much a solution of the fever as desquamation of the cuticle. However, I cannot help looking upon this as very often the effect of improper remedies.

The treatment in all such cases should be decidedly antiphlogistic. The propriety of venesection will of course depend upon the general excitement and the local symptoms. Diaphoretics form

an essential part of the treatment when the excitement runs high. The bowels should be kept regular; but the less irritating or drastic the purgative, the better. If, as often happens, the urine coagulates at an early period of the fever, or that albumen exists in the urine in ever so minute quantity, it has appeared to me advisable to avoid mercury in every shape.

When anasarca supervenes the solution of the disease, diuretics are then necessary. If the urine be coagulable or contain albumen, we should avoid both squills and mercury, and, as a general principle, saline solutions. Not but that the anasarca swellings may often subside under such treatment; but they only give place to more formidable diseases — hydrocephalus, or inveterate muco-pulmonary discharges, frequently terminating in phthisis, in children; or ascites, tympany, or hydrothorax, in adults. At either age, the consequences may be diabetes, or some organic disease of the kidney or bladder. The diuretics which I have found most successful are digitalis and colchicum, but particularly the latter, which I think suited to serous urine in every instance, or whatever the nature of the disease. It does not appear that Dr. Christison used the colchicum in any of the cases of dropsy which he has published, as exemplifying that species arising from diseased kidney. Squill and mercury were used; but I should infer from the report itself that digitalis and supertartrate of potash seemed to agree best, and proved the most effectual remedies. If there be much fever venesection should be practised, and repeated until this is subdued. This, too, will be more especially necessary if the urine be high colored; and contain urea in abundance, with or without excess of lithic acid, or that it produce a speedy and sensible acid re-action on litmus. But if the urine be opalescent, contain little or no excess of urea, and have an alkaline re-action, then local bleeding, or if general bleeding be necessary, the bleeding should be small and repeated, will mostly suffice. With the diuretics, and in this case, colchicum is decidedly the best, tonics are extremely useful. In prescribing tonics we should recollect the distinction between tonics and stimulants: the latter are highly in-

jurious. Of tonics I know of none equal to the preparations of iron. Of these the phosphate, the tartrate, and the *tinctura ferri ammoniat*, appear to me superior to every other; and I question whether their efficacy be attributable to their tonic, so much as their restraining powers.

The mildest and most effectual preparation of colchicum, I conceive to be an acetic extract; and I am indebted to my friend Dr. Prout for first directing my attention to this preparation, which I believe to be peculiar to himself. I have, however, adopted a different mode of making the extract to Dr. Prout. He recommends evaporating the acetum colchici of the pharmacopœia to the consistence of an extract. I prepared an acetous infusion of colchicum by macerating the bruised seeds in distilled vinegar, filtering, and evaporating the filtered liquor to the consistence of an extract. I think thus prepared it is more uniform in strength, activity, and effect; and, what is perhaps of equal importance, does not produce those unpleasant effects which frequently result from the powder or other preparations.

These principles of practice will be found to apply to other diseases attended with serous urine as well as to dropsies. When the urine is alkaline, or shortly becomes so, then we may expect catarrhal or similar discharges from the bladder; of course I conclude the practitioner capable of determining whether the "phosphatic diathesis" prevail or not. In such cases we must carefully avoid the exhibition of alkalies and alkaline earths, or their salts prepared with a vegetable or destructible acid. These circumstances are not sufficiently attended to in practice. The phosphoric or muriatic acid in such cases is infinitely preferable. I prefer in most cases the former.

There is no subject, perhaps, of more importance than the state of the urine in diseases of the kidneys and bladder. The prescribing of alkalies and their carbonates in most descriptions of urinary irritation, has been productive, in many instances, of great mischief. This error has probably arisen from a too general interpretation of a passage in Dr. Marcet's work on calculous disorders*.

The common sedlitz powder is now so universally taken that to this circumstance alone may be fairly attributed much of the greater tendency to, and even prevalence of, vesical disease, at the present day. I know of nothing more calculated to induce disease of the bladder than an alkaline condition of the urine; and there is no more effectual means of inducing this condition than the practice now so common, of swallowing saline effervescing draughts in which the alkali is saturated with a vegetable acid. I know one case in which a man brought on a severe and long-continued catarrhal discharge from the bladder, attended with serous urine, by using carbonate of soda to render hard beer brisk and mild. In these cases the purest water, and free from all saline impregnations, is most desirable. If the use of distilled water could be adopted, it would be still preferable.

Opium, or some other narcotic, will, generally speaking, be necessary. The most effectual of this class, after opium, is the hop and hyoscyamus. They seem to exert a restraining effect upon the morbid secretions of the kidneys. I have long confined my practice to the acetate and sulphate of morphia in these cases. With these I generally give a proportion of extract of hyoscyamus, or of hop. The dose of morphia is from the one-twentieth to the one-tenth of a grain daily; and in these doses I have derived every advantage, without those vertiginous affections which are stated to result from larger doses. I have been now, for the last four or five years, in the habit of using morphia, and for the last three years to the almost total exclusion of opium; and except in two instances, one of which was not immediately under my care, but that of a friend, I cannot bring to my recollection any unpleasant consequence as resulting from it. But even in these cases the vertigo soon disappeared on discontinuing the medicine; but in one the return to its use was invariably attended with these effects*.

If the serous condition of the urine be well-marked, or of long standing, cupping the loins with the insertion of issues in the region of the kidneys, will prove highly beneficial. I have seen the quantity of albumen rapidly

* Second edit. pp. 173, 174.

* Hyoscyamus seemed to agree with this individual better than any other narcotic.

diminished, and in some cases even wholly disappear, after cupping and the insertion of issues. It will often happen that the albuminous condition of the urine, and the diseases associated with it, will, after the above discipline, yield to remedies which had been previously long tried in vain.

I had intended to illustrate the principles of pathology and therapeutics advocated in this paper by the history of a few select and appropriate cases. But these remarks have extended so much beyond the limits which I at first intended, that I shall be obliged to defer this history till a future opportunity. The principles, such as they are, are the result of patient and laborious inquiry, and for which ample opportunities have presented, in many instances, through the kindness of professional friends.

Chelmsford,
1st December, 1829.

COLLEGE OF SURGEONS.

[Communication of a "Professional Friend," concluded from our last No. page 369.]

HEN I am desirous to record the names of some of the surgeons composing the court of the college, who framed the regulations by which its business is transacted, and conducted its affairs since the attainment of the new charter, whilst their characters are still remembered by the profession; declaring, at the same time, my own conviction that abler men could not have been selected to decide upon the measures likely to conduce to the increase of the knowledge and respectability of our profession. The gentlemen to whom I particularly refer, were Mr. Chandler, of St. Thomas's Hospital; Mr. Keate, of St. George's (the uncle of the present surgeon); Sir Charles Blicke, and Mr. Long, of St. Bartholomew's; Sir William Blizard, of the London Hospital; Sir David Dundas, Mr. Cline, and Mr. Norris.

A committee of seven members held a great number of meetings for the consideration of the bye-laws. Their meetings often lasted from eight in the evening till two o'clock in the morning. Each regulation was deliberated on at three meetings, and the committee, convinced of the necessity of reflection and

repeated consideration, suggested that no alteration should be made in the laws without undergoing the same process.

The utmost frugality in the expenditure of the College is observable: indeed these gentlemen deemed the honor and gratification of directing the affairs of the college, so as to lead to results beneficial to the profession and the public, to be a sufficient recompense for all their labors. There is one most important point, in which I am convinced the council has conscientiously discharged its duties. It has selected, in conformity to its bye-laws, the best-informed and most respectable surgeons, according to their seniority, provided they have evinced a knowledge of anatomy and physiology, qualifying them critically to examine candidates in these initiatory and most important professional studies, or have attained great experience by superintending the practice of large hospitals. In making this selection, persons of respectable character and ability must necessarily be occasionally passed by, and they will consequently be dissatisfied with the conduct of the college. That the council may occasionally err in their selection, is not improbable; but their error is chiefly that of granting too free an admission.

It seems impossible to adopt better means of selecting from the profession persons best qualified to judge of the measures by which its prosperity is to be promoted. The electors and the elected are brought together from remote hospitals and parts of the metropolis with very little personal knowledge of each other, and with no community of interest or feeling except that resulting from the object of their convention, the endeavour to promote the prosperity of the profession. The election is decided by ballot, and the judgment of the majority must prevail.

The profession is possessed of a striking proof of the foregoing assertion, for two gentlemen, avowedly hostile to the measures of the college, have been of late elected members of the council. Each has proposed his own alteration of the regulations, and the council has met and deliberated upon them, and conceded to their opinions as far as the circumstances of the times permit; for the profession must be aware, that unless the legislature has decided whether and in what way it will accord to the

profession the means of obtaining anatomical knowledge till it shall become known where anatomy can be effectively taught, no regulations likely to be permanent can be made; and that the regulations of the college must always vary with the circumstances of the times.

It seems to be admitted that the council is chosen in the best way possible, were it merely for directing the general affairs of the profession; their competency, as examiners, alone is doubted. Now, though the young may think themselves better informed than those of more advanced age, it would be a waste of time to attempt to shew that the Court of Examiners is composed of men most capable of deciding upon practical points in our profession; and there is in general so many persons who have been teachers of anatomy and physiology included in their number, that it would be very unlikely ignorance in these elementary and highly important subjects should escape detection.

It is not my intention to represent the College of Surgeons as a perfect establishment, but it contains in itself the means of approximation to perfection; which it is probable will gradually be adopted. I merely wish the profession to consider what they would in reason desire. Would they wish to adopt the customs of other countries? If so, it will be found that the colleges of other countries appoint professors, to teach the different branches of medical science, and likewise examiners. The colleges here, too, might appoint some of their junior members, who have manifested a perfect knowledge of the latest additions and improvements made in anatomy, physiology, and those sciences which are the foundation of medical knowledge, to examine into the proficiency which candidates have made in them; whilst the seniors remain examiners on the practical points of the profession. If, also, certain members of the medical profession think that an especial examination in any one of its departments be essential to the public good (and I here refer to what has been of late said with regard to midwifery), it is in the power of the Colleges of Medicine and Surgery to appoint a committee of such persons as they know to be highly informed in the theory and practice of midwifery to examine such of their own members, or

other persons, as may be desirous of examination, and grant them testimonials of qualification. Under these circumstances, no alteration in the authorities for the regulation of the medical profession, already constituted and considered by the government and by the legislature, can reasonably be required.

The opinion of the medical profession must have great influence with respect to those subjects which they are supposed to have considered and to understand. It is therefore desirable that they should thoroughly consider what they wish to ask of parliament, with reference to the means of acquiring a knowledge of anatomy; without which their profession would be a curse instead of a blessing to society. At first, the members of the committee appointed by parliament to inquire into this subject, seemed to be clearly of opinion that no new law or positive enactment was requisite. It seemed only necessary to repeal the pains and penalties inflicted by some old laws upon those who had a dead body in their possession; laws which led to the severe sentences lately passed upon Mr. Cooke, of Exeter, and Mr. Gill, of Liverpool; laws which there is reason to believe that our ancestors made, not so much from dread of dissection as from that of sorcery.

As many paupers are supported during long illness and infirmity, and consequently may be said to die greatly in the public debt, it is not reasonable to expect that the additional and useless expense of burying their remains should be incurred, when, by making them subjects of anatomical instruction, the debt due to public benevolence would be amply repaid. It therefore only became necessary that parliament should enact that it shall be lawful for the directors of eleemosynary institutions to consign the bodies of such paupers as have no friends, in the first place, to the teachers of anatomy, and afterwards to those of the medical profession who may require them; upon condition of the receiver signing an obligation to keep the transaction from public knowledge, and so to dispose of the body as to give no offence or disquiet to any person who is not of the medical profession. By this mode of proceeding no feeling will be violated, and the disinterment of those bodies

which their relatives have piously consigned to the grave, will be no longer necessary or continued. Moreover, as there are persons who, by the commission of crime, have forfeited that respect and protection which the public extends to all its members, and who die in prisons, the legislature might further authorize the superintendants of these establishments to dispose of such bodies in a similar manner.

It can scarcely be supposed that parliament would appoint the public to be the distributors of the dead, and load their act with a cumbrous apparatus of irresponsible commissioners, were it not from the influence of the members of our profession, exerted directly or indirectly, from the supposition that they might possess an interest with the commissioners, and induce them to act in a manner contributory to their own private interests. In opposition to the simple permission given by such an act of parliament as I have supposed, for obtaining subjects for anatomical instruction, it is said that it denies to them the rites of Christian burial. The sacraments and ceremonies of the church are all designed for the benefit of the living. The pious committal of the relicts of our relatives to the grave, cannot but have a beneficial influence upon the survivors. The bodies for which we apply have no friends, and it would be superstitious in the extreme to suppose that "the bringing home of bell and burial" could be of any avail to the dead. Indeed the valueless nature of the dead body is strikingly exhibited by the words of the burial service: "We therefore commit the body to the ground; earth to earth, ashes to ashes, dust to dust."

Should, however, the legislature deem the burial of the remains of bodies received for dissection to be indispensable, the obligation signed by the receiver may be made to extend to the interment of them in consecrated ground. Moreover, should the legislature not be satisfied unless the distribution of friendless paupers and criminals was conducted by persons of responsibility, it appears best to entrust that responsibility to the Colleges of Physicians, or of Surgeons, in London, Edinburgh, and Dublin, and to agents of their appointment in the Provinces; for then, were any partiality shewn in the distribution, an appeal might be

readily made, and the error corrected. It seems impossible to conduct these transactions as in other countries, where bodies are brought to the schools and returned for burial with very little dissection, and sometimes merely with the performance of a single operation. I cannot believe that the medical profession intend to ask of the legislature of our own country that prodigality of supply which is granted by the police of other countries.

In opposition to the simply permissive act of parliament, which, I believe, was at one time contemplated, it is said that it would greatly distress the feelings of the friendless poor, whom necessity compelled to seek admission into our eleemosynary establishments: but abundance of facts contradict this supposition. In other countries, those admitted into hospitals know that their bodies will be dissected, and yet they do not hesitate to solicit admission. Even in this town, there is an hospital where the patients are fully apprised that such may be their lot; yet the applications for admission are as redundant as to any other hospital. The poor go into workhouses for a maintenance, and into hospitals for a cure. They think not of dying till the time arrives, and then, from failure of intellect, their thoughts are in general transitory, feeble, and unimpressive; or if otherwise, they seem quite indifferent about worldly concerns. As every one must know, that, after death, the body will be annulled by corruption, it cannot appear important whether it undergoes this change before or after dissection. There is reason to believe that few would object to be dissected, but from motives associated with their feelings during life. They do not choose that their persons should be exposed, or their diseases scrutinized, and perhaps made the subject of unfeeling remarks or communication. Such objections cannot apply to patients in poor-houses or hospitals. Those who may examine the body after death, have no personal knowledge of the party during life. They receive it as the remains of a fellow creature, who died of those diseases "which flesh is heir to."

LATIN EXAMINATIONS.

[By the subjoined letter, we perceive that our old friend at Monkbarns has become a member of our profession. We trust he will find it more profitable than looking for "relicts."]

To the Editor of the London Medical Gazette.

SIR,

I HAD not proceeded far with your leader of the 14th, when I doffed and wiped my Dollands to satisfy myself that our trusty courier, Jacob Caxon, had not put the Mechanics' Magazine, instead of the Medical Gazette, into my hands. A glance at your motto, "*licet omnibus*," speedily assured me that I was in possession of your valued hebdomadal, which has never failed since its introduction into this remote borough, to interest and instruct, by its varied and useful information, that portion of the community whose office it is to watch the first appearance and final exit of poor mortals. On the present occasion, however, the feelings with which I perused your remarks on "Latin Examinations," were not of that pleasurable kind which your judicious handling of medical politics and ethics was wont to inspire. I was determined, nevertheless, to hear you out; and it was with some consolation I found, what indeed I might have expected, that in wishing to abolish the practice of Latin examinations, you by no means desired to dispense with what has usually been deemed an essential pre-requisite to our professional education — *videlicet*, a competent acquaintance with classical literature. But, Mr. Editor, while I freely acquit you of all intention to obliterate or bring into contempt the little learning that still lingers among the followers of Esculapius, I cannot but opine that such is the *tendency* of the remarks in which your reasoning, on this subject, is conveyed. The zeal with which you have uniformly supported the dignity of our profession, and the authority so justly conceded to your opinions in matters involving its best interests, are but so many motives with me for examining the correctness of views which might, perchance, prove prejudicial, if not fatal, to its existence as a science.

The vivacity of your attack upon the

ancient usage in question, and the array of arguments, authorities, denunciations, and threats, with which it is supported, are, I must confess, rather daunting; but if I can turn your advanced position, I shall consider myself harmless both from your *railleurie* and that of Moliere, who, in his "*Malade imaginaire*," I humbly submit, had the medical charlatanry of the day in his view, as, in his *Tartuffe*, he scourged the dissemblers who dishonoured a sacred calling. I would therefore venture, at the risk of a bone bruising on your critical wheel, to defend what you are pleased to designate a worse than useless remnant of barbarism.

The great objection which you urge against the present practice of our universities is, that the extent of a candidate's acquirements is attempted to be ascertained in a language with which he cannot be supposed to be so familiar as his native tongue, and which, being a dead language, is insufficient, since science has become intricate and extensive, for the communication of our ideas. Could the charge of poverty thus brought against the Latin be established, I should be the last to wish to see perpetuated an usage which would inevitably retard the diffusion of knowledge. But is penury, indeed, among the defects of that language which served the masters of the world in promulgating their will to universal empire; which, "in the high and palmy state of Rome," was the language of common life, of polite society, of philosophy and the muses? Such *were* its powers and capabilities you will doubtless say, but it is now obsolete and dead. When we consider how much the English is indebted to the Latin for its elegance and flexibility, the "dead lion" might, methinks, have been spared this kick. Still no respect for prostrate greatness would induce me to compromise the interests of science by retaining a defective medium of communication, either out of gratitude for past services or veneration for dignified antiquity. But, admitting the gigantic strides which science has made in modern times, it will, I think, be difficult to shew that it has outstripped the power of the language of antiquity to record its progress and express its principles. Though, as a spoken language, the Latin is mute in our drawing-rooms, it is still capable of being made

the language of the academy; and though dead in one sense, does it not speak in those immortal works which survived the wreck of empires, and saved, through a long night of intellectual darkness, the most precious treasures of antiquity—its literature and science, with the taste for high attainments? Did it fail the great Bacon in pointing out the road to truth; or Newton and Galileo in recording their success in attaining it? And have we, from the days of Wolfbrand Oldenbuck, my respected ancestor till now, been wanting in proofs that it presents the scholar and philosopher with a pure and fitting vehicle for communicating the higher branches of knowledge? All this you will be ready to grant, but still ask, “why cramp ourselves with the fetters of a foreign and dead language when we can boast a vernacular tongue, at once the most rich, copious, and expressive perhaps in the world?” The answer I will give still in your own, on this occasion, most cogent and befitting words. “As a branch of general knowledge, and as the best basis for the superstructure of a complete medical education, we hold classical literature to be perfectly indispensable to the accomplished practitioner, both as a gentleman and a scholar. A familiarity with the classic writers will impart to his mind an elegance and elevation of sentiment—will improve his reasoning powers, and bestow on him a command of language scarcely attainable from any other source.” But what has this to do with the barbarous system of Latin examinations? Much, I think, Mr. Editor. The system which you so reprobate is in all our universities a main criterion of a candidate’s familiarity with the classics; and in some, and those not the least frequently called upon to confer medical degrees, the sole test of his having held that communion with the fathers which you regard as essential to his edification. Abrogate the usage in dispute, and one incitement to the study of classical literature is withdrawn. The competitors for the *summi honoris* will then come to the trial as “innocent of Latin” as the candidates for certificates from Apothecaries’ Hall. One of your intelligent contributors, Mr. Bacot, will perhaps inform you how much the youth of our profession were disposed, when no obligation existed, to study the language of Celsus for its own sake. If,

in order to get rid of examinations in a dead language, and yet ensure the requisite modicum of classical erudition, you would insist on a previous course of the “humanities,” you must first succeed in moving the senatus to a revision and reconstruction of their statutes, which might not be an easy task. To take a lesson from the practice of “the worshipful” would, I fear, little mend matters, it being as easy to produce an interlinear translation of Gregory and Celsus as of the London Pharmacopœia.

I consider it no objection to the retention of examinations in Latin, that many who undergo them fail in exhibiting that perfect acquaintance with the language which you admit to be desirable. The same individuals would probably make but a sorry display in their mother tongue. Were the objection worth any thing, I see no reason why Oxford and Cambridge should not be razed to the ground, because a great majority of those who resort to them leave within their halls the little learning they carried there from school.

To expect perfection in human institutions would be as unreasonable as chimerical. Our profession, like every other, admits of improvement, and, perhaps, reform. It has often been taunted with attempting to veil its doctrines in mystery, and impose upon the vulgar, great and small, by forms and ceremonies. The works which have in every age been published to the world to explain, though not always satisfactorily, its principles and practice, might, I conceive, have saved it from this reproach. While we take care that no just grounds shall exist for such imputations, nor any fitting opportunity be lost for judiciously correcting its defects, let us not, in our eagerness to improve its condition, dismantle it of those becoming ornaments which add to its dignity and strength. To “the lowest classes of society,” whose suffrages you invoke in aid of your hostility to ancient usages, I am willing to allow due credit for shrewdness and intelligence in the affairs of life without making them arbiters in science: their importunate “*cui bono*,” selfish, gross, and earthy, was never yet the rallying cry of true philosophy. The enlightened and refined alone can properly appreciate the connexion between ornament and utility. Let us, therefore, fervently depre-

cate, as the worst of evils, any measure which might tend to disunite them in our profession. "The feather that adorns the royal bird sustains his flight; strip him of his plumage, and you fix him to the earth."

Thine,
JONATHAN OLDBUCK, M.D.

Monkbarns,

MEDICAL GAZETTE.

Saturday, Dec. 26, 1829.

"Licet omnibus, licet etiam mihi, dignitatem *Ar-
tis Medicæ* tueri; potestas modo venendi in pub-
licum sit, dicendi periculum non recuso."—CICERO.

ROYAL COLLEGE OF SURGEONS IN IRELAND.

WE publish this week, in another part of the Gazette, the latest regulations of the Irish College, but we regret that our space will not at present permit us to offer more than a few brief remarks on them. An opportunity, however, may speedily arrive, when we shall take a comprehensive view of the state of professional education in the sister kingdom; a glance, such as we conceive will not be uncalled for, inasmuch as it would seem that considerable darkness prevails on this side the channel, with respect to the state of the profession in Ireland. It may be generally known, perhaps, that the College of Surgeons enjoys, by charter, the privilege of arranging what education a candidate must receive, and what qualifications will entitle him to a diploma. But we suspect that it is not generally known in this country, that the said College, unlike that in London, professes to be the fountain head of surgical and (as it would now appear) of *medical* instruction also: in fact, that the chief school of surgery in Ire-

land *belongs to the College*, and that its conductors, its partners in trade, and the leading men of the Council, are identical.

Our readers may also remember, that some time ago there was a loud and general outcry against the College, on the subject of apprenticeships: no gentleman could by any means obtain the sanction of letters testimonial, who had not served an apprenticeship to a *regularly educated surgeon* (a term by which the members of the College modestly understood themselves exclusively to be designated); in a word, that an apprenticeship was the only door by which admittance into the surgical profession could be obtained. Well, then, the outcry against this abuse proved too strong for them—it was triumphant. A new charter has since been conferred; the College has been "thrown open," as it is called, and apprenticeships are no longer indispensable; at least, such was the ostensible and generally accepted tenor of that document. Now let us see what the first authenticated manifesto of the Council puts forth; and if it appear, that, with professions of liberality, they have adopted a happy contrivance to keep their doors shut—and by such a distribution of the requisites for each class of candidates, to turn the balance visibly in favor of the *old regime*—must it not be inferred that the whole proceeding of getting a new charter was a mere mockery—a dextrous means of evading the just demands of the public?

Candidates for the license must be either registered apprentices or independent students. We will contrast a few of the documents required from each.

Apprentice.

Indenture of five years' apprenticeship.
Thirty guineas.
Certificates of attendance on hospitals, lectures, dissections, &c. for a time not specified.

Non-Apprentice.

Certificates of six years' study.

Sixty guineas.

Certificates of three years, or five winters' hospital attendance, three courses of anatomy and physiology, three of surgery, three of dissections and demonstrations, two of chemistry, one of materia medica, one of practice of medicine, one of midwifery, and one of medical jurisprudence.

Can there be a moment's hesitation on which side the advantages lie, and that these enactments are calculated to perpetuate the vile system of apprenticeships? An indenture for five years is set off against *six years' study*; and an attendance on hospitals and lectures for a period which has been left in a most convenient obscurity, against an active and expensive course for a carefully defined space of time. What would be thought of such a monstrous regulation had it emanated from Lincoln's-Inn Fields?

To the course of education itself we can have no objection—though we fancy the pilots are putting to sea with engines at work, under a high and dangerous pressure; let them add botany, natural history, and all the other physical sciences, to their list; let them even profess themselves to be regular physicians as well as regularly educated surgeons; let them, in fact, indulge their spirit of improvement to the utmost, (though, by the way, surgery has never yet been separated from the barber craft in Ireland), yet it is to us, we must confess, not a little extraordinary that in their ardor they by no means despise the system of perpetuating servitude by the continuance of apprenticeships. There must be something extremely seductive and satisfactory in it to reconcile them to the palpable and notorious degradation of entering their profession as they should a mechanic trade. Nay, we are aware

that there is a tempting bonus held out for the encouragement of the system; so much so that we must say, had we a young friend about to enter upon his surgical courses in Ireland, we should by all means recommend him to be bound to a master.

But we have done for the present. We shall only add that our curiosity has been excited not a little by the mysterious inuendo in the first regulation, which alludes to certain "privileges reserved for apprentices." That the fees for hospitals, lectures, dissections, &c. demanded of registered pupils are on a diminished scale, we know; and that the whole of the qualifications for letters testimonial are suited to the convenience of both master and apprentice, is manifestly clear; but what those other "privileges," reserved for apprentices, are, we can only guess. We shall not, however, venture to publish our conjectures until we have obtained some more particular information. When we shall have attentively studied the by-laws of the college at large, we will resume the consideration of the subject.

Extract from the By-Laws of the College, relating to the Examination of Candidates for Letters Testimonial; published by order of the Court of Censors.

I. CANDIDATES shall be admitted to an examination for letters testimonial as apprentices, and shall be entitled to the privileges reserved for apprentices, if they shall have been duly registered as such on the College books.

II. Every apprentice so registered shall be admitted to an examination for letters testimonial, if he shall have laid before the Court of Censors the following documents:

1. A certificate signed by the President, or Vice-President, and two of the Censors, that he has passed an examination as to his acquaintance with the Greek and Latin languages in the following books,—viz. the works of Sallust, the first six books of the *Æneid* of Virgil, the Satires and Epistles of Horace, the Greek Testament, the Dialogues of Lucian selected by Walker, and the first four books of Homer's *Iliad*; or a certificate from his tutor that he has entered as a student Trinity College.

2. His indenture of apprenticeship, with a certificate signed by the member or licentiate to whom he has been indentured, that he has fully and perfectly served such apprenticeship for the full term of five years.

3. A receipt shewing that he has lodged, to the credit of the President, and for the use of the College, in the Bank of Ireland, the sum of thirty guineas.

4. Certificates of attendance on hospital practice, on lectures on anatomy and physiology, surgery, the practice of medicine, chemistry, materia medica, midwifery, and medical jurisprudence; and of the performance of dissections, and attendance on anatomical demonstrations.

5. A thesis, essay, or dissertation in Latin or English, fairly engrossed according to a prescribed form, upon any of the following subjects:—Anatomy, physiology, surgery, practice of medicine, chemistry, materia medica, midwifery, or medical jurisprudence; or, in place of such dissertation, a series of cases collected in the hospital in which the candidate has attended, illustrated by comments, or observations.

III. Every candidate who has not served an apprenticeship shall be admitted to an examination for letters testimonial, if he shall have attended lectures, or hospitals, for three winter seasons at least, in Dublin, London, Glasgow, or Edinburgh; and if he shall have laid before the Court of Censors the following documents:—

1. A certificate signed by the President, or Vice-President, and two at least of the Censors, that he has passed the examination as to his proficiency in the Greek and Latin languages, as prescribed for the registered apprentices: or a certificate from his tutor that he has entered Trinity College.

2. A receipt shewing that he has lodged, to the credit of the President, and for the use of the College, in the bank of Ireland, the sum of sixty guineas.

3. Certificates shewing that he has been engaged in the study of his profession, in some hospital, or school of surgery, or medicine, for the full term of six years.

4. Certificates of attendance on a surgical hospital, containing at least 50 patients, during five winter seasons of six months, or three years, if such attendance shall not have been perfected during the winter seasons.

5. Certificates of attendance on three courses of lectures on anatomy and physiology, three courses of lectures on the theory and practice of surgery, and the performance of three courses of dissections, accompanied by demon-

strations; also certificates of attendance on two courses of lectures on chemistry, one course of lectures on materia medica, one course of lectures on the practice of medicine, one course of lectures on midwifery, and one course of lectures on medical jurisprudence.

6. A thesis, or series of cases, as enjoined for registered pupils.

IV. No certificate shall be received for attendance on lectures, delivered in Ireland, unless from teachers in schools permitting the visitation of the Court of Censors, and receiving their sanction.

V. No certificates shall be received from teachers who deliver lectures upon more than one distinct subject, as hitherto allotted to professors in colleges and universities. This regulation, however, shall not exclude the certificates of a teacher who delivers separate, perfect, and distinct courses on anatomy and physiology, and on the theory and practice of surgery.

VI. No certificate shall be received for attendance on lectures on anatomy and physiology, unless such lectures shall have been delivered upon at least five days in each week of the winter session, between the 1st of October and 1st of May; nor on the theory and practice of surgery, on chemistry, practice of medicine, materia medica, or midwifery, unless delivered within the same period, or at least three days in each week. The two courses delivered in London, and there called autumn and spring courses, shall, however, be considered equivalent to one winter course of six months, as delivered in Dublin and elsewhere.

VII. Every candidate producing certificates of attendance on lectures, or hospitals, previous to his examination for letters testimonial, shall be liable to be examined respecting their authenticity; and if he shall refuse to answer thereupon, or if it shall appear from his answers, or from any other information obtained by the Court of Censors, that he has not attended such hospital or lectures with regularity, or according to the regulations laid down by the College, he shall not be admitted to an examination for one year; or should it be proved that he has presented a forged certificate, or a certificate obtained by causing some person to personate him and attend for him, he shall never be examined; and if such fraud shall be discovered after the candidate shall have obtained letters testimonial, he shall be expelled, and such letters shall be withdrawn, and shall be given up by him to the College, on demand in writing signed by the Secretary, or, in default thereof, proceedings shall be had against him on his bond.

VIII. The examination of every candidate for letters testimonial shall be held in the presence of the members and licentiates of the College, or such of them as choose to

attend; and the Secretary shall, by regular summonses, give at least four days' notice of such examination.

IX. Every candidate for letters testimonial shall be solemnly examined on two several days, in anatomy and physiology, in the theory and practice of surgery and medicine, in chemistry, and in materia medica. Candidates shall be expected to perform such surgical operations, or make such dissections on the dead body, as the Court of Censors may require; or they shall be called upon to explain any anatomical preparation which the examiners may lay before them.

X. In case a candidate shall be rejected, and shall appeal to the Court of Assistants, such appeal, stating that he considers himself aggrieved by the decision of the Court of Censors, shall be lodged within eight days from the date of rejection, and the candidate shall be admitted to examination within fourteen days from the date of such rejection. The examination before the Court of Assistants shall be conducted, in every respect, as the examination before the Court of Censors.

XI. A candidate for letters testimonial who has been rejected, shall not be admitted to another examination, except upon his appeal, in a less time than one year from such rejection; and he shall then be required to lay before the Court satisfactory evidence of his attention and opportunities of improvement, subsequent to the period of his rejection.

XII. The Court of Censors shall be authorized to examine candidates for letters testimonial, who have not been educated in strict conformity with the above by-laws, but who shall produce evidence of having received a professional education equivalent to that required by the College; provided such candidates apply for an examination, and lodge their certificates and other necessary documents with the Secretary, previous to the 1st of May, 1830. The Court shall also be authorized to receive certificates issued by competent teachers previous to the 1st of May, 1829, notwithstanding any regulation to the contrary in the above by-laws.

Midwifery Diploma.

XIII. The mark distinguishing practitioners in midwifery in the printed lists of the College, shall not be affixed to the name of any member or licentiate of the College subsequent to the 1st of November, 1829, unless he shall have obtained the license or diploma of the College, authorizing him to practise that branch of surgery as herein after specified.

XIV. A Court of Examiners, consisting of a chairman, deputy chairman, and six members, shall be elected by ballot, on the first Monday in January in each year, to examine such members or licentiates as be-

come candidates for the diploma in midwifery; any four of which court, with the chairman or deputy chairman, shall be competent to hold such examination.

XV. Every candidate for the diploma in midwifery shall be admitted to an examination, if he shall have laid before the Court the following documents:—

1. A receipt shewing that he has lodged, to the credit of the President and for the use of the College, in the bank of Ireland, the sum of five guineas.
2. Certificates of attendance on two courses of lectures on midwifery, of six months duration each.
3. A certificate of attendance on an established lying in hospital for a period of at least six months, or a certificate that he has been a resident pupil for six months in some established dispensary for lying-in women, and diseases of women and children; such hospital or dispensary to be approved of and sanctioned by the Court.
4. Satisfactory evidence that he has conducted thirty labour cases at least.

XVI. Candidates for the midwifery diploma, shall be examined on the anatomy and physiology of the female generative system, the theory and practice of midwifery, and on the diseases of women and children; and if approved of by the Court, shall receive a license or diploma to that effect, to which the College seal shall be affixed. Should a candidate be rejected, he shall not be admitted again to an examination until a period of three months shall have elapsed, and he shall then be obliged to produce satisfactory evidence of his having been engaged in the study of this branch of surgery subsequent to such rejection.

WM. AUCHINLECK, President.

October 23, 1829.

LEGAL MEDICINE.

A CASE has recently occurred in France in which a body was disinterred *seven years after burial*, and the fact of the individual having been *poisoned by arsenic* determined by chemical examination.

M. Orfila was asked, last June, if a body, removed from the grave after such a lapse of time, could possibly afford proofs of poison having been administered; and if so, in what manner such an investigation was to be conducted? To this question he replied, that it was very probable the body was already almost entirely reduced to ashes, but that, nevertheless, if a sort of blackish coom was found at the sides of

the spinal column, chiefly in the dorsal and lumbar regions, such mass might be analysed in the manner pointed out in his work on Toxicology. MM. Ozanam and Ide, physicians at Lyons, where the supposed murder had occurred, were requested by the legal authorities to proceed to the disinterment of the body of a man whom they suspected had been poisoned by his daughter in 1822, in the department of Ain. They accordingly did so, and found that nitrate of potass and hydro-sulphuric acid were acted upon by the suspected matters as by arsenic. The grave had been dug in a dry gravelly soil, in which there was a little sulphate of lime; and to this circumstance must doubtless be attributed the remarkable state of preservation in which the body was found. The coffin was entire, formed of thick planks of fir, which internally were quite dry. Although more than seven years had elapsed since the interment, the body was recognized by the priest, by the grave-digger, and even by some of the national guard who had assisted at the ceremony, and fired over the grave. All remembered the spot, and the individual was identified by the hair which yet remained, and by the teeth, all of which were still in their sockets, except one particular tooth, which he had lost before death; and lastly, the joiner recognized the coffin, which had been constructed with unusual care, being intended for a person of distinction. The head, trunk, and limbs, were entire, so that the stature could be measured. The chest had sunk in, the heart and lungs were blended together, and presented the appearance of a dark ointment. The whole was without smell. The entire trunk was removed, the head and extremities being regarded as unnecessary to the investigation. The portion thus reserved for examination weighed nine pounds; of this, two pounds were set aside for a second series of experiments, in case those made on the first should prove unsatisfactory.

In these investigations, MM. Ozanam and Ide went on the supposition of arsenic being the poison—this being the one employed in the great majority of cases. The matters above-mentioned were boiled, the fluid evaporated to dryness; and the residuum thus obtained dissolved in distilled water. This produced a deep-coloured liquid, which

was but imperfectly deprived of its hue by chlorine. The distilled water charged with this extract was again evaporated to dryness. At the same time, four ounces of nitrate of potass, placed in a matrass, were exposed on ignited charcoal. The suspected matter, well dried and rolled into little portions, was introduced. Each time this was done, a deflagration was perceived. It was then allowed to cool, and the residue again dissolved in distilled water. This solution was saturated with nitric acid, and afterwards subjected to the usual re-agents, all of which indicated the presence of arsenic. Some small portions were treated with vegetable charcoal, introduced into a glass tube, and then heated. They gave out aqueous vapour; soon after which, small grey-coloured and brilliant points were seen. A grain of metallic arsenic was thus obtained. Another portion, treated with hydro-sulphuric acid; furnished sulphuret of arsenic; and this, heated and acted upon by caustic potass, afforded a portion of shining matter, which was easily dissolved in distilled water, by directing upon it a current of oxygen gas. By these various experiments, the fact of a considerable quantity of arsenic having been administered was thus demonstrated at the end of seven years, affording a striking illustration of the importance of toxicology in forwarding the ends of justice.

HOSPITAL REPORTS.

HOTEL DIEU.

Anomalous Exanthematous Eruption on the Neck and Lips—Death—Blood in the Lymphatics.

A MAN, aged 36, of middle size, and rather robust, experienced for some days general indisposition, with considerable prostration of strength, without any apparent cause. He next perceived that the upper part of the neck, on the right side, became swollen, and covered with phlyctinæ, over a space equal in size to that of a five-franc piece. In the centre of this spot the epidermis was raised, and discovered the dermis, which was of a brown colour. At the same time the lips swelled, and became

covered with minute miliary vesicles. There was anorexia, fever, and oppression: the patient seemed to have the commencement of a severe attack of erysipelas, or even of malignant pustule. However, the general symptoms as yet indicated nothing alarming. The patient was ordered to be watched, while simple beverages and attention to diet were enjoined. He died the same evening, without having presented any other symptom.

Examination.—The cellular tissue beneath the exanthematous patch on the neck was ecchymosed, but no other change was perceptible at this part. The stomach had elevated patches scattered over it, similar to those which are met with about the ileo-cæcal valve. The rest of the alimentary canal was free from disease. The body was sent to La Pitié for dissection, where some pupils having removed the abdominal viscera, were proceeding to study the muscles of the loins and pelvis. In raising the peritoneum which covered the lower part of the spine, they found on the last lumbar vertebrae, and in the hollow of the sacrum, a set of vessels highly injected, and of a deep red color. Their disposition, numerous anastomoses, and connexion with the lymphatic ganglia, left no doubt of their nature, and it was perceived that all this system of vessels was filled with blood. Whence came this liquid, or how had it found its way into an order of vessels which does not naturally admit it? None of the neighbouring organs had been the seat of hæmorrhage; neither veins nor arteries were altered; in a word, there was nothing to explain the phenomenon. These lymphatics were traced upwards with great facility, into the thoracic duct, which was injected in the same manner, even till its junction with the subclavian vein, which was in its natural state. The liquid from the lymphatics was analysed by M. Barruel, and ascertained to be really blood; and a drawing was made from the preparation by Dr. Carswell, so as to preserve the appearances.

Changes in the lymphatic system become less rare, in proportion as investigations relating to it multiply. Besides the facts recorded by M. Andral, others have been collected in England and Germany, which prove that the thoracic duct is susceptible of alterations no less severe than numerous: it has been found filled with pus, with softened

medullary degeneration, &c.; obliterations of the duct have been noticed; partial dilatations and strictures, or narrowings, of a greater or less extent; its parietes have been found ulcerated; thickened, and altered in various other ways. But the particular pathological fact which we have above related, is regarded by MM. Dupuytren, Breschet, and Sanson, as unique.—*Lancette Française*.

MEATH HOSPITAL, DUBLIN.

Case of Tracheotomy in the Cynanche Laryngia.

SATURDAY, Nov. 28, 1829.—Miles Brady, æt. 24, a labourer, admitted into the hospital, under the care of Mr. Porter, with the following symptoms.

Great dyspnoea, the respiration having a sibilous or whistling sound, accompanied by severe exacerbations, particularly at night. Harsh ringing cough; almost total loss of voice, the trachea moving upwards and downwards in the neck, and the muscles acting with almost convulsive energy and rapidity. Great tenderness on pressing the neighbourhood of the larynx. On examining the fauces no appearance whatever of inflammation. The face is flushed and swollen; the lips have a tinge of lividity; the eyes white and prominent; there is an indescribable expression of anxiety in the countenance; pulse 100, small and weak.

Such were the symptoms observed at 10 A.M., the time of the patient's admission, when he was ordered to have a bolus, containing ten grains of calomel, every third hour, and to be bled immediately until syncope should supervene.

At 2 o'clock Mr. Porter saw the patient again, and found the symptoms aggravated to such a degree that life could not continue many hours. The cough incessant; and the respiration so impeded that it could be heard in another ward, at the distance of several yards from the patient's bed. The operation was determined on instantly, and only a sufficient time allowed to summon the assistance of the other surgeons of the hospital.

At half-past 3 the patient's bed was wheeled into the operating theatre, and placed in such a position as to throw the light on the neck. An incision was made, commencing near the sternum, and carried upwards to the cricoid cartilage, exactly in the central line of the neck. This was carried deeper between the muscles, and then a particular difficulty in this operation occurred. The blood, mixed with air, bubbled and gurgled from the bottom of the wound; and it was evident that the deep parts of the neck were emphysematous. On proceeding deeper still, the difficulties increased. Persons who form their ideas of

this operation from books, or even from dissection on the dead subject, will scarcely conceive the depth of wound often necessary in the living. In this instance the knife had penetrated to the depth of two inches ere the trachea was laid bare, and then it was almost impossible to fix this tube so as to permit the excision of a portion of it. After some time a semilunar incision was made in the windpipe, and a tube passed through it.

The patient did not seem to experience the instantaneous relief that has been described as occurring after the operation. On the contrary, the irritation produced by the presence of the tube, and perhaps by the trickling of some blood into the trachea, continued for a considerable time; and it was only after the lapse of an hour and a half that he felt relief, and enjoyed a composed and tranquil sleep.

Nov. 29th.—Patient expectorates a good deal of mucus through the wound. Pulse above 100.

Venæsection, and to continue the calomel in ten grain doses, as already ordered.

Nov. 30th.—Pulse 105, and soft; mouth slightly affected by the mercury. Respiration slightly impeded by the inspissated mucus in the wound; great emphysema of the neck, extending below the clavicles. The stethoscope indicates intense bronchitis over the entire lungs.

Venæsection to sixteen ounces. Pills of Calomel and Antimonial Powder every fourth hour.

Dec. 1.—Was bled a second time last night, and slept afterwards for six hours. Face, to-day, flushed and anxious; complains of pain in swallowing, and very considerable uneasiness in the throat.

Bled to-day again. The blood is cupped and buffed. A small portion of the trachea, which was loose and coated, like a valve, was removed this evening.

Dec. 2.—Patient has had little sleep, but yet is better. He lies quite tranquil; breathes freely through the wound, and gives but little trouble. Expression of countenance improved; complexion of a bright florid red; emphysema as before; bronchitis diminished.

Medicine to be continued.

Dec. 3.—Patient's mouth much affected by the mercury. He makes signs that he can swallow without much difficulty. Pulse 84, and soft; stethoscope indicates that there is no bronchitis; emphysema as extensive as ever.

Venæsection, and the medicines to be continued.

Dec. 4.—Mouth does not appear to be so sore as yesterday. Pulse 84; slight bronchitis; emphysema diminished. On closing the wound for a moment, the difficulty of

breathing does not seem to be in the slightest degree relieved.

Bled to twelve ounces; blood deeply buffed. Calomel and opium every third hour.

Dec. 8.—The symptoms during the last three days have been nearly stationary. On this day the salivation is very great; and on closing the wound the patient speaks with a very raucal tone. The respiration not relieved; an abominably fetid odour from the wound; occasional spasmodic dyspnoea, with paroxysms of coughing. Expectoration from the wound abundant, not puriform.

The mercury is discontinued.

Mr. Porter was this day understood to say that he did not anticipate the best results in the termination of this case; but whatever these results may be, shall be made known to the readers of the Medical Gazette.

WESTMINSTER HOSPITAL.

Erysipelas.

JAS. BURGESS, æt. 49, admitted Nov. 30, under Mr. White. Ten days ago he first perceived a small puffy sort of lump on the back of the forearm; he is quite unconscious of ever having received any injury on that part. It increased in size a little, and was very painful on the third day after he first perceived it. On the fourth day his whole arm was inflamed and swelled; he had medical assistance, when it was fomented and poulticed, and he was ordered half an ounce of salts every night. It still continued growing worse, and when he was taken in, the whole arm was swelled to nearly double the size of the other; the skin red, hot, and tense, more especially on the forearm, immediately below the olecranon.

He says he has always lived remarkably regularly. He is a labouring man. His health has not been good for many years, having had frequent attacks of illness. He had not been drinking or committing any excesses to which he can attribute his present attack.

R Infus. Sennæ, ℥viii.

Pulv. Jalapæ, ʒij.

Magn. Sulph. ʒss.

Potassæ Supertart. ʒij.

Sodæ Carb. ʒj.

M. ft. mist. p̄ cap. coch. ij. 4tis horis.

Dec. 1st.—The tenseness and inflammation of the arm is in some degree relieved. Bowels have been very freely purged, and there is a small opening in the upper part of the arm, which discharges a little. Tongue clean. Pulse quick and feeble.

2d.—Mr. Harding made an opening to

day in the under part of the arm below the elbow, and a small quantity of purulent matter escaped. On passing the finger into the opening, the integuments were found separated, for two or three inches round. Poul-tice to be applied at night, and fomentations continued during the day. Continue mixture thrice a-day.

3d.—The wound has discharged very copiously, and is much less hot and inflamed. Tongue clean, bowels open, appetite moderate.

7th.—The inflammation and swelling of the arm have nearly subsided.

10th.—The arm is now very quiet, and he does not suffer much pain from it. There is a great discharge, and he feels extremely weak. Tongue tolerably clean; bowels open; pulse 70 in the minute, wiry and jerking.

R Quinin. Sulph. gr. xvj.

Acid. Sulph. d. 3j.

Infus. Rosæ, ʒviij.

Ft. mist. coch. ter in die sumend.

Full diet, and a pint of porter daily. Appetite is tolerably good.

14th.—The quantity of discharge is diminished; his appetite is good, and he is rapidly regaining his strength. The opening is filling up with granulations; and all inflammation has entirely disappeared.

Wax as an application to Ulcers.

The application of wax to old ulcerated legs has been practised here with great success within the last few months. In every instance it has rapidly improved the character of the sore, and brought on a disposition to skin over, and in the greater number of cases the ulcers have healed in a much shorter time than could have been calculated with the ordinary application—indeed it has succeeded often when all the usual dressings had been tried, and failed. The following is one out of many, where its beneficial results have been experienced.

Samuel Buxton, æt. 35, admitted Oct. 28, 1829, under Mr. Lynn, with a large irregular ulcer, about six inches in length, and from three to four in breadth, extending down by the side of the shin, with excavated edges, and dark unhealthy-looking granulation. States that for the last two years he has been a labourer, but was previously in the army, and served in India for four years, during which period he lived a most irregular life, drinking spirits whenever he could get them; sleeping in the open air, frequently on marshy ground. He had an attack of ague three years ago, and has been subject to it ever since. About two years back he was invalided, and sent to England, and on his passage, during one of the paroxysms, he states that a sore on his leg broke out, where there had been one some time before, occasioned by grazing it against an iron bedstead. He was confined four months to his bed, during which time two pieces of bone

came away. On his arriving in England, he was sent to Chatham, from whence he was discharged cured.

Several months ago several small ulcers appeared, which gradually increasing, became one continuous sore. It was poulticed with linseed meal for a fortnight before he came in, and he had taken some aperient medicine.

Oct. 29th.—He is an unhealthy-looking man, emaciated, and says he suffers much from his leg, which is very painful. A poultice was applied on his admission, and a dose of house medicine given him. This morning the ulcer has been coated with wax, and the following mixture ordered:—

R Infus. Gent. C. ʒviij.

Acid. Sulph. d. 3ij. M. ft. mist. et cap.

Coch. ij. ter in die.

31st.—The character of the sore is much improved, the granulations have a more florid and healthy appearance, and the edges are less excavated. Repeat the wax.

Nov. 2d.—The hollowed edges are now completely filled, and skin has formed round them.

4th.—On removing the wax this morning, the granulations, though extremely healthy, were found to be very high; the most elevated portions, therefore, were rubbed over with the argentum nitratum, and the wax applied again.

6th.—The granulations are nearly level now, and skin forms rapidly round the edges.

10th.—His health is still not good. Appetite bad, and he is much troubled with a cough.

R Pil. Plummeri, gr. v. alt. n. sumend.

15th.—His general health is improved, and his cough is less troublesome. The ulcer is skinning over rapidly.

Dec. 10th.—The leg has been dressed regularly with the wax, and has continued gradually but steadily improving. There is now merely a small ulcer of very healthy character, about an inch in length, and which is evidently healing very rapidly.

GUY'S HOSPITAL.

Fractures of the Leg.

We present the following cases of fracture of the leg to our readers, in illustration of the good effects of the straight position, with a splint on the inner side of the leg, as practised in France by M. Dupuytren, when compared with the plan recommended by Pott and others, and generally adopted in this country, viz. to keep the leg semiflexed on its outer side.

CASE I.—While J. M. æt. 30, was walking over Westminster bridge, with his cart and horses, he slipped from the high pavement, and fell, his right foot turning inwards under him, so as to produce a frac-

ture of the fibula, about an inch above the point of the outer malleolus, through the tibio-fibular joint, and one of the inner malleolus, from above to below and outwards, extending into the ankle joint. The inner malleolus, thus split off, was separated from the shaft of the bone, by the effusion into the joint consequent to the contusion.

When admitted, immediately after the accident, on Sept. 21, under Mr. Key, the nature of the injury was apparent; but there was so much tumefaction, that leeches were applied before putting the limb in splints. His leg was maintained in the straight position, on pillows, for a few days. The leech-bites ulcerated, requiring the use of poultices, and rendering the subsequent application of the bandages rather inconvenient. These were applied on Oct. 1—a splint extended from the knee to the inner ankle, padded thickly to about half way down the leg, so as to press on the upper-part of the tibia alone, and a small pad pressed the inner malleolus outwards; next a long splint reached from the back of the thigh to the heel, having a foot-piece attached, and well padded; including these a roller was applied over the foot and ankle, in the figure of 8 mode; and another fixed the apparatus at the knee, beginning two-thirds up the leg.

No bad symptom followed.

On the 15th October he could bear the leg to be handled without inconvenience, and could move his ankle without pain, indicating pretty firm cohesion of the fractured bones. Four days afterwards all splints were removed, and the limb merely bandaged.

On Oct. 29, five weeks and a half after the reception of the injury, he left the hospital with a very straight leg, the ankle-joint being only stiff in some degree.

CASE II.—J. T. a stout healthy-looking man, fell on Thursday evening, Oct. 29, over some bricks, by which his foot was bent under him inwards. On the following morning he came to the hospital, with his leg greatly swelled and hot. A fracture of the fibula, about three inches above its point, and one of the tibia, separating, but not displacing the inner malleolus from the tibia, were discovered.

App Hirud. xx. cruri, et postquam foveatur, adhibeatur constanter, Lotio Plumbi diluta frigida. Cap. Col. c. Cal gr. xv.

On Nov. 11, after the repeated application of leeches, the tumefaction was sufficiently subdued to allow the application of splints. As in the above case, a splint was put on the inner side of the leg, but with a foot-piece in addition, so that slight inversion of the foot was allowed, and the roller was applied so as just to catch the point of the outer malleolus, and counteract the muscles, which drew the fractured extremities towards the tibia.

On Nov. 30 his leg was quite straight, and

the bones very firm, permitting motion of the foot in all directions without pain.

On Dec. 7 he was discharged from the hospital quite well, all splints having been removed for two or three days.

CASE III —This was a compound fracture of both bones, produced by a piece of timber falling on the leg of T. W. æt. 11. The tibia and fibula projected in front, each by a separate wound, at about two inches and a half above the ankle. The foot and ankle were greatly arched inwards, requiring a splint reaching from the knee to the foot on the outer side, to obviate this, and which kept the leg in a good line. The wounds were poulticed for some days, and on the 15th one was quite healed, and the other nearly so. Soon after this, however, acute erysipelas attacked the leg, which excited fear for the ultimate result, and retarded the progress of the cure in a great degree. Matter formed in the neighbourhood of the wound, and the boy became so restless as to render the splints, applied loosely on account of the erysipelatous inflammation, of little advantage.

On Nov. 23 the sores were nearly healed, and the bones quite united and firm; but there was a very small sinuous communication with the lower portion of bone, which was denuded of its periosteum.

On the 25th the sores were healed, the bones firmly united, and the limb admirably straight. Pasteboard splints now superseded the others, and he was allowed to get up.

In five more days, or exactly ten weeks and a half after the time of the accident, the boy left the hospital quite well.

CHALLENGE.

LAST Tuesday evening, Mr. M'Christie, a reporter in the hire of the Lancet, whose name has recently appeared in our pages in connexion with Mr Earle's correspondence with Wakley, sent Mr. Mills—we presume the printer of the Lancet—to require an explanation from Dr. Macleod, as reputed Editor of the Medical Gazette, of certain charges of falsehood against Mr. M'Christie, made, as we stated, on the written authority of Mr. Earle. As our readers may suppose, the right of Mr. M'Christie, or any other hireling of the Lancet, to claim the privileges of a gentleman, was treated with contempt.

W. WILSON, Printer, 57, Skinner-Street, London.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

LECTURE XIV.

Ulceration and Granulation.

THE matter of an abscess, gentlemen, advances to the surface of the body, or it escapes from those internal cavities which have external outlets—such as those of the digestive, the respiratory, the urinary, or generative organs—in consequence of a removal of the intervening substance by the absorbents. A similar advance to the surface of the body is observed in the case of aneurism; in the progress of which, not only are the soft textures which intervene between the aneurismal tumor and the external surface of the body removed, but even bones, when they come in the way of the aneurism, are removed. All matters pass away, with great facility, by absorption.

This [exhibiting a preparation] is an example of aneurism in the ascending aorta, where you observe a large chasm in the sternum, through which the aneurism has advanced to the breast externally. This again [exhibiting another preparation] is an aneurism of the descending aorta, and you perceive that the ribs and side of the vertebral column are in like manner removed by absorption.

Aneurism advances to the surface in the same way as other tumors formed deep in the body—that is, at a considerable distance from the external surface; they make their way outwards by the gradual removal of the parts which cover them. This is not only the case in tumors which form in the soft parts of any of the limbs, or of the trunk, but even in those which form in the interior

of the cavities. For example: if a tumor forms on the surface of the dura-mater, although the progress externally is resisted by the skull, it will cause absorption of the bone, and come through.

This [exhibiting a specimen] is an instance of the kind, where the tumor has been formed on the external surface of the dura-mater; the internal surface of which is entire, but there is a part of the skull removed, and you see the tumor has made its way, and shews itself externally.

In all these various cases there is a gradual removal of the parts which intervene between the disease and the external surface, or between the disease and the surface of some one or other of the mucous cavities of the body. The parts are removed by absorption. This particular process is what is called by Mr. Hunter "*progressive absorption*;" it is the removal by the absorbents of the intervening parts in the progress of the disease to the surface of the body. The term "*progressive*" absorption is, perhaps, not very happily chosen, to designate any particular kind of absorption; because all absorption is necessarily progressive, and this kind of absorption is not progressive in any higher degree than any other sort. But the truth is, that, in this instance, the advance of the disease to the surface of the body is progressive, and that, I suppose, is what Mr. Hunter meant. At all events, this particular kind of absorption is not more progressive than any other.

The removal of the parts by absorption, in this case, is preceded by some degree of inflammation—that is, there is some previous thickening and consolidation of the textures, which are afterwards to be removed by the absorbents, so that the abscess or aneurism remains entire. There is no escape of matter from the cavities into the textures that are progressively removed. The contents of the aneurism, or abscess, are retained in the cyst, even during their passage through the intervening textures, owing to the parts by which they advance being consolidated by a

slight degree of adhesion which precedes the absorption.

A portion of the substance of the body may be removed, so as to occasion an external breach in the surface, or a portion of the surface of some internal organ may be removed in the same kind of way. The same process is observed in the separation of a slough from the contiguous living parts. You find that a groove takes place first along the margin of a dead part; that this becomes deeper and deeper, and at last it extends throughout the whole depth of the mortification, so as completely to separate the dead part from the living. This process is called by Mr. Hunter "*ulcerative absorption*,"—that is, the removal of a part by the absorbents, where an external breach of the surface is produced by the loss of substance; or, simply, it may be called *ulceration*. Now, this kind of absorption, like the former, is preceded by inflammation. The part is first red, hotter than usual, slightly swelled—interstitial deposition takes place in it, by which the textures are consolidated and thickened, and by which the blood-vessels and absorbents, which, in the progress of the absorption, will afterwards have to be separated, are completely blocked up. Now in ulcerative absorption—that is, if the process take place in the course of the blood-vessels and absorbents which are in part to be removed, they must be divided, and the adhesive inflammation which precedes the act of ulcerative absorption obliterates those vessels, so that no escape of fluids takes place, though the process of ulceration actually divides them.

Now in the case of ulcerative absorption, there is a formation of matter in the breach of the surface, which is produced by it; and that circumstance distinguishes this from the preceding case of progressive absorption. In progressive absorption there is no formation of matter as the parts are removed, nor is there any in what Mr. Hunter called *interstitial absorption*. But in ulcerative absorption—that is, where a part of the body is removed, so as to produce an external breach, or loss of surface—there the removal by absorption is accompanied by the formation of matter in the surface that is thus made.

Ulceration, then, may be stated generally to be the removal, by the absorbents, of a portion of the body, causing an external breach of the surface, or a solution of continuity, as it has been technically called, and accompanied by the formation of matter.

The process of ulceration does not consist in erosion, as it has sometimes been supposed—that is, the textures of the body that are removed are not chemically acted upon by any acrimonious or corrosive properties in pus, because pus possesses no such property; it is a perfectly bland and mild fluid—it has no solvent power over the textures of

the body. In fact, if pus had this power, there would be no limit to the mischief produced by ulceration. Ulceration, when it has commenced upon the surface of a sore, is moistened by pus; and if pus possessed the properties I have mentioned, it would destroy the surface, and there would be no end to the extent of devastation.

The process of ulceration, and the circumstances under which it arises, as well as the general phenomena of the event, are very various. These varieties depend on differences of structure in the parts which are the seat of ulceration—on differences in the nature of the inflammation which produces it—that is, whether it is common or specific; and on differences in the constitution and state of health of the individual who is affected. All the textures of the body are susceptible of ulceration. We see this exemplified when mortification has attacked an entire limb, and when the separation takes place by a natural process. Suppose, for instance, the foot and lower part of the leg were mortified, and the mortification stopped at the middle of the leg; you would see that the skin, the cellular membrane, the fascia, the muscles and tendons, blood-vessels and nerves, and, lastly, the bone itself, are all penetrated by the process of ulceration. A groove forms on the external surface, and extends through all the parts in succession; and finally will separate the bone itself; and thus you have a kind of natural amputation performed by the process of absorption. The ulceration acts externally upon the skin first, then through all the soft parts, and subsequently through the bone; so that you see the whole of the tissues that enter into the limb are liable to absorption. But all parts of the body are not equally liable to it—the skin is most prone to ulceration. Hence the great variety of ulcers we have an opportunity of seeing on the external surface of the body. The mucous membranes come next in order; then the cellular tissue, the bones and articular cartilage, and although, from the conformation of these textures, you might suppose they were not so likely to ulceration, yet they are frequently attacked by it. Fascia, tendons, and ligaments, are perhaps the textures which least readily run into ulceration; and hence it is that, in the progress of matter to the surface of the body, when an abscess takes place under them, they do not yield readily to the ulcerative process.

We are best acquainted with the phenomena of ulcers as they take place in the skin, because there all the circumstances of the process are open to the senses. The remarks, then, that I have to make respecting the history of ulceration, as it occurs in the skin, are applicable, with some modification, to the same process occurring in other textures of the body.

I have already mentioned that ulceration

is preceded by inflammation of the part. We find that a state of inflammation, and generally considerable pain, precedes the formation of an ulcer in any part of the skin. The skin becomes red, preternaturally hot, more or less swelled, and then we find that it begins to ulcerate at one or more points. We observe that the cuticle becomes loosened; or perhaps it may be elevated into small vesicles on the part. The cuticle thus detached assumes a whitish appearance, and the part is apt to take on a livid hue. When the detached and loosened cuticle is separated, we see a visible breach in the surface of the skin. There is a more or less deep excavation, in consequence of the removal of a part of the cutaneous texture. There may be one spot, or several contiguous spots; in the latter case, they join together, and form one common ulcerated excavation; and this extends in circumference and also in depth—that is, it becomes larger in all its dimensions. We find when we examine the parts, that so long as the absorbent process is going on, and before the process of restoration has commenced, there is a manifest excavation or loss of substance. We see clearly that some portion of the body is removed, there is a chasm, and this chasm shews the nature of the process by which it has been effected; it has a kind of irregular appearance, and the textures of the body which are exposed by the extension of the ulcerative process, are, in some measure, partly recognizable at the bottom of the ulcer. The surface of the ulcer is, perhaps, of a dirty whitish or yellow hue. There is sometimes the appearance of fibres, or threads, on the surface, and they are generally covered with a thin serous and sometimes rather bloody fluid. The edge of the ulcerated excavation is sharp, and defined on the margin of the skin, which is red, hot, and painful.

This is the appearance which an ulcer exhibits in a spreading state as long as ulceration is going on, and before steps are taken to repair the mischief it has produced. Unless the process of ulceration is put an end to, it soon goes through the skin, and destroys it. It then makes a chasm in the cellular membrane it may pass through, and affect the subjacent soft parts; and, in fact, there is no limit to the extent to which it may go, if the process be not arrested.

When the process of inflammation is checked, and when the removal by ulcerative absorption of the constituent textures of the body is put an end to, then we have the restorative process by which the breach is to be filled up. The process of restoration is accomplished in nearly the same way under four different circumstances; that is, *first*, in breaches produced by ulcerative absorption in the external surface of the body;

secondly, in the ulcerative surface which is produced after the separation of a slough; *thirdly*, in the exposed cavity of an abscess, when this has been opened, or when it has become exposed by bursting; *fourthly*, in ulceration on the surface of wounds in which there is loss of substance, or where the sides of the wound are not brought in contact. The process of restoration, by which the surface is restored in each of these four cases, is essentially the same. The new matter by which the chasm is to be filled up consists of a soft red substance, which, on the surface, is elevated into small red prominences, of a roundish or pointed figure, differing in size, and these, as I have mentioned, are kept moist on the surface by a secretion of pus. These small prominences are called *granulations*, and the process itself, taken altogether, is termed *granulation*. Although the secretion of pus is a common circumstance in the process of restoration, by which the chasms produced by ulceration are to be supplied, I believe we cannot say it is an universal one. It takes place in a great majority of instances, but I believe that in the case of ulceration of the articular cartilages of bones no secretion of pus is to be observed; and in ulceration of the cornea we cannot observe any thing like the secretion of pus. The presence of pus then is not a circumstance that can be admitted into the definition of ulcer. The definition of ulcer must probably turn merely on the breach in the surface of the body or of any organ—the chasm or solution of continuity that is produced by ulcerative absorption. We may, however, add, that the circumstance, in the majority of instances, is attended with the formation of pus.

Now the explanation of the restorative process is this: coagulated lymph is effused on the surface of the chasm or ulcer, and this coagulated lymph speedily becomes organized; that is, the blood-vessels, and absorbents, and nerves, are prolonged into it; and in this manner the surface of the body, where it has been interrupted by ulceration, is regenerated. Here you see the process is similar to that which goes on in inflammation. I have mentioned, that under inflammatory action, coagulated lymph is effused into a part; that the lymph is a receptacle in which blood-vessels, absorbents, and nerves, are formed; and thus the parts are thickened or increased in bulk. In the process of granulation, by which ulceration is to be healed, you have the same circumstance; that is, you have effusion of lymph on the surface of the body, and you have blood-vessels, absorbents, and nerves, extending into it; so that the process, in this view of the subject, is similar to that which takes place in inflammation; in fact, they are hardly to be distinguished from each other.

You will not be surprised to find that increased action in the neighbourhood of the part goes on. The surrounding parts are redder than the rest of the limb, and there is sometimes a sensible increase of heat in the part. Dr J. Thompson says that he attempted to measure the comparative temperature of the part where this process is going on by a thermometer; and he found, in an immense number of instances, the thermometer rising two degrees higher in this than the contiguous parts of the same limb.

I have mentioned that the terms *coagulated* and *coagulable* lymph are used rather vaguely in pathology. The truth is, our knowledge is not sufficient to enable us to apply these words in their strict senses. Heretofore the substance by which the breach of an ulceration is filled up—that which is effused on the serous membranes when they are the seat of inflammation—that which is poured into the interstices of a part under adhesive inflammation, was called coagulable lymph. This term seems to imply that the lymph would be in a fluid state, but that it admits, under certain circumstances, of coagulation. Mr. Hunter generally preferred the term coagulated lymph, because we find, when the substance is produced, it coagulates. Thus, on a serous membrane it forms a mass of a soft consistency, yet in a coagulable state. Dr. J. Thompson (whose lectures on inflammation contain a valuable collection of facts relating to the process, and to all its varieties and effects—in fact, it is a work you would find very useful, though I believe it is out of print; and I think it would be a valuable service to the public if he were to reprint it, with such an addition of new matter as he may have obtained subsequently to the time at which the former edition was issued), speaks of this lymph under the term of *organisable* lymph, because it is a striking circumstance in its character that when it is effused in a particular part of the body it speedily becomes organized, so as to constitute some new substance or addition to the body. I merely make these observations to shew that, under the name of *lymph*, or *coagulable* lymph, or *coagulated* lymph, or *organisable* lymph, the same substance is meant which has been mentioned repeatedly in the course of these lectures.

This, then, is considered to be but the basis of that soft reddish substance constituting granulations, by which sores are to be healed. I have mentioned to you that soon after this is deposited in the sore or ulcer, it shews blood-vessels, absorbents, and nerves, so that it becomes regularly organized. Respecting the existence of blood-vessels in these granulations, you can be but little at a loss for a proof of that circumstance. In the first place there is a red color, which de-

pends on the presence of blood, and this is uniform throughout the substance. This shews that it not only possesses blood-vessels but that it is extremely vascular. Sometimes the color is florid and bright; sometimes it is more livid—more like the venous blood. However, by looking attentively on the surface, you can see blood-vessels in the granulations with the naked eye; and if you employ a slight magnifying power, you see them in great abundance. If the part in which the ulceration is situated be injected, the sore is rendered completely red, which would not be the case if there were no blood-vessels; and a slight degree of violence inflicted on the ulcer causes it to bleed, and proves that the blood-vessels are of considerable size. We have an evidence of blood-vessels in the new part by the pus which the granulations are capable of furnishing. It is equally clear that these granulations possess *absorbents*. Frequently the granulations diminish in size, or are entirely removed from the surface; and we find, that by absorption, certain medical substances applied to the sore produce their peculiar effects just the same as they would if taken into the stomach. Thus, if mercury is applied, in the form of ointment, or in other shapes, to an extensive sore, as in that of red precipitate, it sometimes salivates persons in consequence of its being absorbed. If arsenic is applied, in a certain form, to a sore, it may produce inflammation and ulceration of the stomach, and, in fact, death; just as it would do if it were swallowed. Opium, applied to a sore, will produce its particular effect by absorption. The existence of *nerves* in granulations is abundantly manifested by the pain. Frequently a very acute pain is produced by offering any violence to them; in fact, a granulating sore is a very sensitive surface. Although the part is newly formed that has thus, as it were, sprung up in the body, yet in two or three days you find that it has a supply of nerves which will render it a very sensitive texture indeed; so that the person will sometimes experience acute pain from the slightest touch of these granulations.

This effusion of coagulated lymph, then, is organized; that is, penetration by blood-vessels, absorbents, and nerves, takes place in a shorter time than we might expect; in fact, so short is the time, that we are at a loss to account for the mode in which the process is effected. When we look at the blood-vessels, and see these produced in twenty-four or forty-eight hours, we are at a loss to explain the mode by which this organization of the coagulable lymph takes place; indeed, we do not know whether the vessels are newly formed in the granulations, or whether it is an extension of the vessels from the surface on which the lymph is deposited;

and we are equally at a loss to know how these granulations acquire their supply of nerves. These are points on which at present we possess no clear or distinct information.

When two granulating surfaces are brought together, and kept in contact, they will unite; the vessels belonging to them assimilate and grow together. The union sometimes takes place rapidly. I remember an instance of a patient brought to this hospital in whom a considerable flap of the scalp had been detached by an accidental wound. It was necessary to apply a poultice to the part in consequence of the injury the surface had received. After a time, under the application of a poultice and other means, the bruises on the surface became clean, and formed a granulating surface. There was now a flap on the scalp, the internal surface of which was regularly granulated,—and there was a corresponding granulating surface on the skull, to which it could be applied. The flap was placed in direct apposition on the surface of the skull which had been denuded, and in twenty-four hours from being so applied, it stuck—to use a common expression—as close as wax; the union of the two in twenty-four hours was quite complete. We had another instance of the facility with which opposed granulating surfaces become united together, in some accidents happening to the eye. When an acrid substance, such as lime, is thrown into the eye, it affects both the surface of the globe of the eye and that of the eye-lids: it produces partial death or sloughing; and, subsequently, ulceration. You have, then, a granulating surface of the lids in contact with the granulating surface of the globe of the eye; and the disposition to adhesion is so great that you often cannot by any means prevent them from growing together; and thus is produced the case which has been designated by the term *symblepharum*, accretion of the eye-lid to the globe of the eye. I have seen instances where accidents have happened, where great pain has been given by keeping the eye-lids distended by art to prevent this accretion, because it is attended with serious consequences, more particularly if they become united with the cornea; in which case it generally involves the loss of sight. I sometimes find it impossible to prevent the lid from becoming united with the eye in such cases.

The process of granulation has been considered to be a property of the cellular substance. It takes place, as I have mentioned, in almost all parts of the body, and you might therefore at first doubt whether it can be considered as belonging peculiarly to the cellular tissue; but this enters into all parts of the body—it is a kind of base, or ground-work, of the structure. It

would be difficult to determine, in such a case, whether the production of granulations belongs simply to the cellular tissue which enters into the composition of particular organs, or whether it is the peculiar product of the organs themselves, such as with regard to the muscular fibres in case of muscles—whether these have any share in forming granulations. We find the granulating process is most abundant and most active where the cellular tissue is in the greatest quantity. This is the case in wounds of the integuments. In wounds produced by burns, for instance, we find granulations formed with great rapidity, and in large quantities, which rise above the surface of the sore; and, in fact, it is difficult to keep them down—to repress them within the bounds we desire for the purposes of union; so that I think the notion first broached by Bichat, that granulation is the property of cellular membrane, is a correct one.

When the granulations in an ulcer rise in this abundant and luxurious way above the margin of the sore, it constitutes what persons, in common language, term "*proud flesh*." When the chasm in the ulcer is completely filled up by this granulating process, then another process remains by which the surface is to be skinned over and covered. The granulations first fill up the hollow of the ulcer to level it with the surrounding sound parts; and we then find a thin small pelicle extended over the granulations from the edge of the sound skin; and when this pelicle is extended over a portion of the granulation, the secretion of pus in that part ceases. At first we observe just a margin of this kind on the very border or edge of the sore. We find the pelicle extended from the edge of the surrounding sound skin over every other part of the sore, and it gradually becomes thicker. At first there is just a thin rim round the margin, that enables this pelicle to extend in circumference towards the centre of the sore; and, ultimately, it covers the whole of the granulating surface. The secretion of pus is then entirely stopped; and, in fact, the sore is said to be healed. The process by which the skin is formed and the pelicle extends over the sore is called *cicatrization*. When the process is complete it is distinguished by something of a red color—by a sort of compactness of texture—by the existence of certain lines and marks which connect the structure to the natural skin. That surface is called a *cicatrix*, which is equivalent to the common expression of *scar*. The cicatrix, or scar, when it is first formed is redder, and apparently more vascular, than the surrounding skin. It is very thin and delicate, so that it easily gives way under a slight application of force, and tears or breaks. But in process of time this great redness disappears;

and, in fact, the cicatrix becomes rather paler than the rest of the skin. The tenderness of the part, which renders it liable to break or crack, is lost; and it becomes harder, and unites more closely together. The ultimate stage of the cicatrization, or formation of the scar, is its losing the peculiar characters which distinguish it from the surrounding skin, so that it is difficult to trace it. The pelicle successively undergoes absorption; and the consequence is, that the surrounding sound skin is elongated and drawn gradually towards the centre of the sore. The granulations are absorbed successively, in proportion as the cicatrization forms over them; and thus the surrounding skin is gradually drawn towards the centre of the sore, becoming, at the same time, more or less puckered in consequence of this drawing together. The effect of this conjunction is to render the cicatrization not more than one-third or one-fourth in extent, compared with the original size of the sore. Thus, a sore that may have been four inches in length, when effectually healed, will finally be reduced to two inches, or one inch in length; and will be proportionably reduced in all its other dimensions.

Now this is a circumstance of great consequence, because the cicatrization which remains after the ulcer, is a part of weaker vitality than the natural surface of the body. Hence it is of course a great object to have the weaker part as little extensive as possible. This absorption of the granulations, and consequent contraction of the scar, and the drawing of the neighbouring parts of the sound skin over the ulcer, accomplishes a very useful end. We see, then, that the granulations which have filled the sore during the healing process, serve the particular purpose of accomplishing this restoration, and then they are removed. They seem to constitute a kind of temporary structure, and are organized until a certain purpose is advanced, and are removed as soon as that purpose is answered.

Now a question has arisen respecting the degree in which the lost parts of the body are reproduced. When surgeons observe a large excavation in a limb, produced by ulceration; when they see granulations arising in it, and filling up the cavity; and the surface then completed by cicatrization, they conclude that the substance that has been lost in consequence of ulceration, and is restored, is reproduced by granulations; and have fancied that in such cases the particular texture—that which had been removed in the process of ulceration, is restored in this way. For instance, that muscle was deposited if muscles had been removed by the ulcer; cellular, or serous membrane, where such had been removed, &c. Others take a different view of the subject, and have

stated that the filling of the chasm in these cases arises from the subsidence of the parts which are preternaturally swelled around; and have even denied the process of reproduction altogether.

That reproduction takes place to a certain extent there can be no doubt, for we see a quantity of new substance, under the term granulation, deposited in the cavity of the ulcer, and filling it up. That there is a deposition of new matter, to a certain extent, cannot be contested. However, the limit of reproduction is easily ascertained in the human body. No entire part is reproduced when once it is lost: the only exception is in the case of the large bones of the body, the shaft of which may be entirely reproduced; which appears in the case of necrosis. I do not know a case in the body in which an entire organ or part is reproduced. We see that, when a finger is cut off, it does not become formed again; or if we cut off a particular part, it is not reproduced. In this respect man, the more complicated animal, differs materially from those of more simple structure. In the lower class of the animal kingdom we find that the reproductive power extends to the restoration of entire and even complicated organs. It is well known, with respect to the crab and the lobster, that one of the great claws of these animals can be reproduced when it is separated, and that fresh claws sprout out from the situation where the original ones had been detached, being first small, and gradually growing larger. Thus entire parts are reproduced in the case of some of the lower animals—such as some of the molluscæ and reptile tribes; and even complicated organs can be reproduced in this way. But in the case of the superior animals, no complete organ, when removed, can be restored.

Parts that are divided can be *re-united*, and the substance, or medium of union, though not exactly corresponding with the original tissue, answers all the purposes of it. A divided muscle, for instance, may have the ends united by new matter, which we recognize when we look at it as something different from the fibrous texture of the original, and it is the same with respect to the tendons; but the muscle and tendon is capable of exerting the same power as formerly. Even cartilage can be re-united.

Farther, the breach that is produced by ulcers can be filled up, and the surface of the body covered by a material that answers all the purposes, though it is not exactly like the natural skin. You can distinguish it by the appearance of a scar or cicatrix upon the external texture of the skin, but the surface thus formed answers the needful purposes. But although the breach of the ulcer is filled, although the loss of substance on the surface of the body is renewed, you do not find that

any of the textures that have been destroyed in the course of the ulceration are reproduced. For instance, if the cellular membrane between the skin of the thigh and the fascia be lost in the course of ulceration, the skin is afterwards closely adherent to the fascia, instead of being separated, as in the natural state. If the skin and fascia be both destroyed, then the cicatrix becomes fixed to the muscles; and in the same way, the skin, or muscle, or both, become firmly fixed to the bone.

With respect to the treatment of ulcers under the circumstances now mentioned, it is necessary, in the first place, to remove the inflammatory disturbance on which the commencement of ulceration and its progress depend. Together with the measures necessary for that purpose, you probably find it expedient to cover the part with a soft poultice. When the inflammatory disturbance is at an end, and when the process of reproduction has commenced, really the surgeon has not a great deal to do: nature performs the restoration, and it is enough, perhaps, for us to take care not to do anything that can interrupt her operations. The part must be kept at rest, and covered in such a way as to protect it from any external influence that might be injurious; it should be covered with a soft poultice, such as bread or linseed. When the process is advanced, these may be supplied by a simple dressing, such as lint plain, or covered with a simple cerate ointment, confined with a proper bandage. This is pretty much what is necessary in the treatment of ulcers generally, and this turns on two points—first, on removing the inflammation, which is the cause of the ulcer, and next on keeping the patient quiet when nature is performing the necessary process of restoration. In respect to the latter point, I need not observe (for it is a rule that belongs to the treatment of all cases) that you must pay much attention to the diet of the patient, giving him those things that will tend to keep him in the best possible state of health.

I should have observed, in speaking of the process of granulation, that a certain degree of exposure of the surface to the air is necessary for its successful prosecution that an entire abscess does not granulate; but when the abscess is come to the surface of the body, and when it has been opened or become exposed by the natural process of ulceration, granulation will commence in it. It never begins to granulate so long as it remains entire. In the same way sinuses do not granulate with facility. While sinuses remain entire, we find it difficult to produce healing. But if we slit up the fistula, so as to make an external surface, granulation then commences; and when it does this we find it necessary to keep the part moist by a soft dressing, in order to

prevent it from uniting at the sides before it unites at the bottom. Hence we find, when abscesses extend deeply, they heal with more difficulty than when they are seated superficially. If an abscess is just under the skin, it heals readily in a short time; but if the abscess is seated deeply—that is, if it be deep in the substance of the limb—then the process of healing does not take place at all readily. It will continue for a long time fistulous, and difficulty is experienced in bringing it to a healing state; so that a certain degree of exposure is necessary to the formation of granulations. When I say a certain degree of exposure, you are not to understand that the part is to be left exposed to the air, or external influence, but I mean it must be left on the surface of the body. You must protect it from the air, which alone, in the tender state of the wound, might interfere with the process of healing.

With respect to the variety of ulcers, and their characters, as well as the different treatment they require, I must postpone that part of the subject till my next lecture.

EFFECTS OF LOSS OF BLOOD.

To the Editors of the London Medical Gazette.

GENTLEMEN,

I BELIEVE every one has heard of some interesting experiments on the effects of loss of blood by Dr. Seeds, but very few have seen the account of those experiments, or indeed know where they are to be found. I think, therefore, you would do a great service to the profession by reprinting them from the accompanying copy of the *Medico-Chirurgical Journal and Review* for "January to June, 1816."

I remain, Gentlemen,

Your obedient servant,

MARSHALL HALL.

15, Keppel Street,
Dec. 26, 1829.

We solicit the attention of the medical reader to the following experiments, which, with others now making, of a similar nature, in different quarters, may lead to more important results than at first sight might be expected.

Concerning epileptic disorders, medical authors, from the commencement of

our science to the present day, have offered many conjectures; but who is not aware that the real nature, and consequently the proper method of treating them, are equally involved in obscurity? As the difficulty and uncertainty of the subject are universally admitted, it is hoped that indulgence will be shown to any attempt, however humble, at throwing light on this interesting topic.

The experiments which are to be detailed, were carefully made, and every circumstance narrated as early as possible, so that their accuracy may be depended on, one or two professors always being present, and subsequently revising the details.

1st Experiment.—The left crural artery of a healthy dog was divided. The struggles were incessant, and greatly accelerated the pulse, but he scarcely seemed to suffer pain, except on the first division of the integuments.

In little more than half an hour from the commencement, the artery of the right leg was divided; the vessel first opened at this time beat very languidly, and in a short time ceased to pour blood, whilst the other continued active to the last.

The heart beat very strongly, and its motions were distinctly perceptible over the whole thorax and abdomen. When the limbs had become cold, and no sign of life was present, the heart still palpitated, the respiration was still laborious. In an hour life ceased.

On dissecting the body, we found the spinal marrow pale, except at the top and bottom, where it was slightly red; on the contrary, the nerves on the points were whitest, and reddish in the middle. The sinus venosi were bloodless. The dura mater cerebri was slightly red, and one rather large blue vessel was seen on the corona.

The substance of the brain was very white, as were all the nerves, except the optics and first pair, whose base was slightly red.

The ventricles were so full of water, that till we had witnessed a similar result in other experiments, we were doubtful of its having been all effused during the experiment.

The right side of the heart was very soft, and contained some black clotted blood; the left was very hard and thick. The viscera were generally pale. Some

of the mesenteric glands were full of a dark coloured liquid.

The palpitation of the heart, the most conspicuous symptom in this case, was very great; it plainly shows, in what state of the body such are likely to happen, and it likewise warns us not to judge of the vigour of the blood from a partial examination, for not unfrequently, when death is just at hand, the heart beats as though it would burst the thorax; at other times, when the smaller vessels are collapsed and deprived of vitality, the larger trunks are powerfully contracting.

Do we not see from this, that, for the due circulation of the blood the heart has need of a vigorous support from the arteries?

The weakness of the body was on a par with the difficulty of breathing, and both advanced with equal steps; hence it appears how intimately the functions of the lungs and blood-vessels are connected.

On dissecting the body, we found that every part was bloodless; especially the different parts of the nervous system.

Why, from opening those vessels, was the body so completely drained of blood? and particularly venous blood?

2d Experiment.—We procured a small dog who had a wound on the right side, penetrating the lungs; from this wound he seemed to suffer little uneasiness during a week that he was in our possession.

The left crural artery was cut. The respiration was very much hurried, and the air was expelled with a loud hissing from the wound in the side. The strength of the heart's motion slowly and gradually diminished: once indeed, a sudden and rapid acceleration of the discharge of blood took place. The weakness of the pulse and dyspnoea were equal, and uniformly kept pace with each other. The legs were alternately bent and extended, and the tongue thrust out of the mouth and again drawn into it. The pupils became insensible to light long before life ceased. In little more than half an hour death put an end to his miseries.

On the following day the body was examined. The dura mater of the brain was colourless and bright. A few small red vessels were seen on the surface of the brain, and amongst its convolutions; its substance and all the nerves were soft and white.

The plexus choroides was of a bright red; there was no blood in the head, except in the basilar veins, which contained a little.

The medulla spinalis could not be properly examined, owing to an unfortunate accident which occurred.

We could not inflate the right lung; the left presented nothing unusual. A few red spots were observed on the stomach. There was a little red blood in the mesentery and omentum. The colon was somewhat contracted, the small intestines crepitated on being handled. The urinary bladder was hard, contracted, and empty.

No one doubts that the integrity of the functions of the lungs is necessary to the health of the body; it appears equally true, that the more readily the blood is received into the lungs and returns through them to the heart, the more completely do we enjoy health.

This fact is of the utmost importance both to the student and practitioner of medicine.

This animal laboured under a wound of the lungs, which impeded their functions and interrupted the ordinary changes of blood; thus, though he lost less blood, he was sooner weakened, and much sooner destroyed, than the subject in the preceding experiment.

The irregularities of muscular action were more evident, both in the voluntary and likewise in the involuntary muscles.

Does not this experiment teach us, that in some cases of diseases of the lungs, an excessive venæsection may prove injurious?

3d Experiment.—An incision was made into the subclavian artery of a small dog. The pulsation of the arteries was immediately quickened, and rose at first to 130, and not long after to 156 in the minute.

The motions of the heart were languid, but regular; they had ceased long before death. In less than a quarter of an hour the pupils were dilated and motionless.

The breathing soon became slow and heavy, and at the same time the neck was slightly twisted. In twenty minutes death supervened.

The thorax was first examined. The right side of the heart was empty, and flaccid; almost all the large veins were full of blood; and in the left side of the heart, and in the abdominal aorta, there was a little dark blood.

Most of the abdominal viscera were pale. In the spleen and pancreas were many dark spots. A very small portion of one of the ureters was ossified. The nerves every where were white and shining. The d. m. c. was colourless. Almost all the sinuses were dyed with blood. Many red and blue vessels were seen among the convolutions of the brain. The plexus choroides was of a bright red. The whole surface of the brain was moist. There was some degree of redness in the spinal marrow, especially in the lower part, as well as of all the nerves. The external coverings of the cord were nearly colourless. No dark coloured blood was to be seen.

In this instance the prostration of the strength was greater and more rapid, and life was sooner extinguished, than in either of the former examples.

The subclavian artery giving off the vertebral, it was to be supposed would, if wounded, speedily affect the head.

Why were the pulsations of the heart so soon and so greatly accelerated? Why so much more venous blood left in the body than before?

4th Experiment.—The carotid artery of a very small dog was opened in the middle of the neck; the blood rushed impetuously to the distance of several feet. In two minutes the strength of the animal sunk, nor did it ever recover vigour.

The motions of the heart, though feeble, were regular; the breathing was hurried, and somewhat irregular.

For a considerable time before death, the body was alternately bent and contracted, in a manner resembling shivering; shortly before death, the breathing became hoarse and laborious.

The cries of the dog were at first shrill, but gradually became feeble; and at last a feeble howl only was uttered: the face and limbs speedily became cold; in ten minutes life ceased. The limbs at this time were flaccid and flexile.

The viscera of the abdomen appeared plentifully supplied with both red and blue vessels. The small intestines were somewhat contracted, and contained three or four lumbrici. The urinary bladder was rugous, and empty. The vena cava was pretty full; and some small dark clots were found in the aorta.

The lungs when inflated were white; but when collapsed, they appeared red-

dish. A small quantity of blood was found in most of the large veins.

The dura mater of the brain was colourless and transparent, except at the falx, where there was a red spot, and some slight adhesions.

The lateral ventricles contained a great quantity of water. The plexus choroides was pale; a few red vessels were seen amongst the convolutions, and one blue one distended on the corpus callosum. The nerves were colourless, except the optics, round whose origins a few red vessels were seen.

The sinuses were quite bloodless. As for the spinal marrow, its tunics were rather red at the top and bottom. No venous blood was to be seen in any part of the vertebral column.

Bichât asserts, that he has found by experiment, that the curvatures of vessels do not impede the motion of the blood; but we are induced to suppose he might have erred, for, on opening the carotid artery, a great quantity of blood was immediately lost, and the animal was, as it were, destroyed at one stroke. It was not so when the *subclavian* was opened; and this vessel, though more curved, is not more distant from the heart.

Bichât, when investigating this subject, chose for the objects of experiment, vessels remote from the heart, as those of the intestines. As we shall see afterwards, a much greater quantity of blood was lost from the carotid when opened than from the aorta itself. Blood was deficient in most of the organs; the nerves were, for the most part, moist and bloodless.

On the opening of arteries, dark or venous-coloured blood almost always abandoned the brain. What reason can be assigned for this fact?

5th Experiment.—All the larger veins of the legs were opened in a small dog. At first the pulse was accelerated; soon after it became slow and languid. The heart's motions, though feeble, were never irregular; and, indeed, long before death, they could neither be seen nor felt. Borborygmi were early heard, and lasted a long time. The breathing at first was hurried; soon it became slow and laborious, at last convulsive. The pupils were frequently examined; they became gradually less and less obedient to the influence of light, and at length ceased to contract altogether. Slight spasmodic contractions took

place, first in the femoral and abdominal muscles, then the head, neck, and fore legs, were likewise powerfully affected with spasms.

At this time a deep sleep seized the animal; he breathed slowly and with difficulty, and for a little time before death, respiration, at intervals, was suspended altogether. Whenever the breathing was strong and quick, the pupils recovered their tone, and the blood was more strongly propelled. In an hour, death closed the scene.

Some degree of stiffness was apparent in the legs, especially the fore ones.

The dissection of the head was first begun. The membranes of the brain were *loaded with turgid vessels*, the larger of which were of a very dark colour.

A bright red spot was observed near the cornua, where some degree of sanguineous effusion had taken place. The sinuses were full of blood.

In all the ventricles there was more or less water effused; the base of the brain, and the eighth and ninth pairs of nerves, were inundated with water; a net-work of red vessels was spread round their origins, and the optics were in the same state. In the cervical and lumbar regions of the spinal marrow, there was a considerable degree of redness. The right side of the heart was full of blood; the left auricle contained a little; some blood was found in the large veins, and a few clots in the thoracic aorta.

The stomach and all the intestines were tumid with flatus. The veins of the mesentery were turgid. The larger veins of both legs being opened, although life was not speedily destroyed, yet it quickly brought on the greatest degree of debility; the slow weak motion of the heart, the languid countenance, the disturbance of all the functions, the apoplectic stupor under which he laboured, all conspire in proving this.

The turgid state of the veins of the head was very remarkable: indeed, throughout the whole body the veins were tumid.

Flatulent distentions of the stomach and bowels frequently distress the enfeebled; and it is well known that they result from excessive evacuations; all aged persons, those labouring under constipation or too great laxness of the bowels, or a hæmorrhage of any kind, are subject to this distressing affection.

6th Experiment.—A healthy young dog was the subject of this experiment. On laying bare the internal jugular veins, we remarked that they swelled much during expiration, and vice versa.

On freely opening these vessels, the blood burst forth with impetuosity, and the animal's strength sunk almost immediately. They had scarcely been opened, when the heart beat strongly and sharply, and a severe panting came on.

The head, neck, and back, were affected with powerful spasms. After two minutes the pupils ceased to contract; and the eyes were twisted towards the nose. In about ten minutes he died.

The lungs were white with different coloured spots; a large black spot was also observed in the diaphragm.

All the veins of the head, neck, and chest, were tumid; moreover, the aorta and its larger branches were slightly stained with blood.

In several of the viscera of the abdomen there were black patches, particularly in the liver and spleen; and in these places they were very weak, and easily torn.

The whole of the intestinal tube, as well as the stomach, was full of flatus. A little blood was found in the mesentery and omentum. The appearance of the brain was very similar to what it was observed to be in the last experiment; a greater number of distended veins were seen, and every thing was overwhelmed with water.

Round the root of the fourth pair was spread a plexus of vessels, and in a less degree round the eighth and ninth pairs.

In every sinus there were clots of dark blood. The tunics of the spinal cord were very red, especially the dura mater. On almost all the spinal nerves there was some degree of rubescence. The sinus venosi contained some clotted blood.

Why did this animal perish so rapidly, as if struck by lightning? The event was not at all in the ratio of the blood lost. All the symptoms clearly showed that the brain was immediately compressed; which conclusion the anatomical examination of the body confirmed.

The contents of the cranium and spinal canal were so gorged with blood that it might at first have been imagined that blood-letting would have saved the animal.

It does not seem out of place to remark here, that in every animal destroyed by blood-letting, and examined by us, we always found more or less of serous effusion in the brain, cerebellum, spinal marrow, and at the origin of the nerves; thus we clearly see why those examining the contents of the cranium have so frequently observed very turgid vessels and water effused, and likewise why venæsection has, in apoplexies, so frequently disappointed the expectations formed of it*.

7th Experiment.—The right jugular vein of a young dog was divided; the flow of blood was copious and rapid for ten minutes, afterwards it became slow; the respiration was greatly hurried, so that he breathed 114, 120, 150, and at length 180 times in a minute.

At these times the discharge of blood was either scanty or ceased altogether, and the breath became cold; but when respiration was less hurried, the pulse became more regular, and the breath warmer. The upper orifice ceased to discharge blood before the lower. The heart's beats were at first unusually quick, soon they became feeble and slow, and sometimes were imperceptible.

In little more than half an hour we cut the vein again, and cleared it of a clot of blood; this appeared to give no pain. The eye-sight soon became obtuse, and not long before death the pupils were immoveable. Almost the whole body was twisted by spasms. After eighty minutes had elapsed, no signs of life were visible.

On examining the dead body, we found the whole of it stiff and twisted. The intestines were much swollen with flatus, the rectum and urinary bladder were contracted and rugous. All the veins of the thorax and abdomen were tumid. The right side of the heart contained a good deal of fluid blood, whilst a little was found in the left side and in the aorta. On the membranes of the brain a wonderfully great number of

* The above appearances certainly could hardly be expected *a priori* from theory; but we are of opinion, that although they were produced without doubt, by *venæsection ad mortem*, yet that a state the very reverse is produced by moderate venæsection, and in the early stage of this extreme blood-letting. The above experiments, however, elucidate the fatal effects of carrying blood-letting beyond a certain point, inasmuch as we then produce what we are anxious to prevent—congestion and effusion.—**EDIT. M. C. T. & R.**

veins was seen. A great deal of water was every where effused. Most of the nerves were pale; the eighth pair exhibited the same appearance as in the last experiment. The sinuses were full of thin watery blood. The membranes of the spinal marrow were plentifully supplied with red and blue vessels; the spinal nerves were covered at their roots with red vessels. At the same time that the breathing of this animal became very rapid and frigid, the flow of blood ceased, and the whole body became cold.

All the moderns, with one consent, agree, that the temperature of animals does not solely depend on the chemical action of the blood in the lungs; but that the powers of life, in some unknown manner, connected with the nerves and nervous system, over-rule and direct all the functions of living animals. What reason can be assigned for the superior orifice ceasing to discharge before the lower?

The loss of sensibility was proportioned to the loss of blood.—When much blood has been lost, or when it has been vitiated, the effects of all stimulants are very much diminished: many facts prove this.

Let a little of any active substance, as alcohol, opium, or digitalis, be given to a person faint from the loss of blood, what do we see happen?

The pulsation of the heart and arteries is slowly and slightly increased, and a gentle degree of heat is slowly diffused over the whole body. On repeating the remedy, the colour, from being changeable, becomes constant. The same may be said of a person labouring under severe typhus fever.

Who is ignorant that if a healthy person should take these substances, the result would be widely different?

Why was the death so tardy in this instance?

8th *Experiment*.—The abdominal aorta of a small dog was nearly divided.

On the left parietes of the abdomen being cut, all the more moveable intestines protruded. The vessel was opened at about half an inch from the commencement of the iliac arteries.

The blood flowed with great force; the motions of the heart immediately became weak, but remained regular till the termination of existence. The breathing, at the same time, was slow

and heavy; and was effected with open mouth and the head thrown backwards, as if the animal panted for breath.

In four minutes time the pupils were dilated, and immoveable; the eyes, however, still retained their splendour. In six minutes he expired.—We first of all examined the viscera of the abdomen.

The intestines appeared plentifully supplied both with red and blue blood: the veins of the liver contained clotted blood. In both sides of the heart coagulated blood was found, in greatest quantity in the left, as likewise in the aorta descendens and vena cava; most conspicuously, however, in the former. The lungs, especially when inflated, were pale; their veins, and likewise the thoracic, were far from empty. The dura mater cerebri was moist, and some few red vessels were ramified through it. Vessels, red and blue, were conspicuous in the other tunics; the plexus choroideus was pale; the ventricles were moist, the fourth was full of serum, a good deal of which was effused round the optics, the accessories, and the eighth pair. The greater sinuses were full. The larger vessels were of a dark colour, while the smaller, and those surrounding the origins of the nerves, were red.

The dura mater of the spinal cord had nearly the same appearance as that of the cerebrum. On removing this tunic, at the top of the medulla, there was a great deal of bright redness; a less degree of it lower down, and at the bottom some larger and darker vessels were seen. There was some degree of effusion within the dura mater, especially at the bottom of the cord.

The nerves were, for the most part, colourless. The fatty tunic was dark coloured, and the sinus venosi contained a little watery blood. Here the strength was quickly and equally broken.

Why was the left side of the heart, as well as the aorta, near the part cut, so full of clotted blood? It is well known, that when any thing opposes the motion of the heart, its parietes are, in the same ratio thickened; but in this experiment, we see the heart and aorta full, when every obstacle to their emptying themselves appeared removed. This shows that there is a necessity for some degree of resistance from the arteries, that the heart may perform its office. As in other instances of arterial bleeding, the intestines were found free from flatus.

9th Experiment.—The abdomen of a dog was opened on the right side by a free incision: all the moveable intestines were protruded, but escaped unhurt. An incision, an inch in length, was made at the entrance of the renal veins. The flow of blood, at first large, soon became less, and at length ceased; it was frequently renewed, but with less violence. The discharge was interrupted at a time when the heart continued to move regularly, and when the orifice of the vein was still open.

Towards the termination of life, the breathing became laborious, and was accomplished with the head raised and the mouth widely opened, and a weak involuntary howl was uttered. The pupils continued to contract for a long time, but at length they became insensible; the muscles of the eyes were spasmodically affected, as were the muscles of the breast and neck, especially the sternomastoideus. The face, limbs, and ears, speedily became cold; and long before death the breath was frigid.

On opening the cranium, great vascular turgescence was perceived in the membranes of the brain, and a deep red spot at the apex. The sinuses were all full. The surface of the brain was moist, and the ventricles contained a good deal of water.

The origins of the second, third, fourth, eighth, and accessory pair of nerves, were in the state so frequently spoken of. Considerable redness of the upper part of the spinal cord was seen.

The nerves of the cervix, and upper part of the dorsum, resembled the greater part of the cerebral nerves; the rest were quite pale. The sinus venosi were full.

The left side of the heart was wonderfully hard, and contained clots of blood; the pericardium was very moist. Abundance of arteries and veins, full of blood, were seen on the mesentery and intestines. The mesenteric glands, and those of the neck, were very tumid. The right kidney was a third part larger than the left.

The death of this animal was the most tardy of any. The blood, on the vein being first opened, burst forth with great violence. Why, we may ask, was the death so slow, when, from opening the aorta and the jugular veins, the fatal event so rapidly took place?

The debility exceeded the ratio of the

blood lost; for the bodies of those dogs which perished from arterial blood-letting, not only lost more blood, but were almost entirely deprived of it. A singular circumstance occurred during this experiment, viz. that the flow of blood ceased while the heart's motion continued uninterrupted. Here we may remark, how surprisingly the symptoms occurring during life accorded in every instance with the dissection. Were the eyes torpid, were their muscles convulsed, the optics, the third, fourth, and sixth pairs, severally and conjointly, were affected in the manner so frequently alluded to; were there at any time spasms of the neck and sides, the upper spinal nerves were found after death to have a net of red vessels spread round their origins, and serum was effused round them. The same may be said of all the other organs of the body and their nerves.

The summary of the conclusions to be drawn from these experiments will, it is hoped, in some measure answer the question proposed for solution; which is, is there any difference between the effects of venous and arterial bleeding? and what is the precise nature of the difference?

The drawing blood from an artery diminishes more especially the quantity of venous blood: therefore arteriotomy is to be preferred when the veins are tumid.

The loss of arterial blood does not speedily disturb the respiration nor the heart's motion, nor does it rapidly break the strength; therefore, where we particularly wish to preserve entire the more important functions, let arteriotomy be had recourse to.

From arterial bleeding convulsions appear not apt to occur; therefore against such affections arteriotomy would most avail.

Blood let from veins does not particularly diminish the quantity of venous blood, but greatly disturbs respiration and the heart's motion, debilitates to a surprising degree, makes the veins every where turgid, and induces convulsions; therefore, when the pulsation is universally strong, as in every active inflammation, venæsection will be most serviceable; however, great caution is necessary in both, lest spasms be brought on.

If an excessive quantity of blood be lost, either from an artery or vein, water

is effused within the brain; therefore, in drawing both, there is need of great caution, lest the tongue become cold, or the patient become sick, or his pupils dilated.

What are the symptoms of effusion of water within the brain?

In the removal either of arterial or venous blood, whenever the pulsations of the heart become very quick and feeble, the blood-letting should be stopped.

Thus, I think, we have learnt, that arterial and venous bleeding produce very different effects.

It is much to be wished that morbid dissections were carried on with the attention and zeal their importance so justly merits; we should then obtain a true knowledge of diseases, and consequently useful and comparatively certain methods of cure. Till the topography of diseases is established, till we ascertain their locality and individuality, and are able, as it were, to lay our finger on the focus of disorder, medicine will be always uncertain, always conjectural. If, as Dr. Saunders so justly and earnestly inculcates in his lectures, all the phenomena of life, (whether in health or disease) depend on the relation between the vascular and nervous systems, and that every living action, whether healthy or morbid, must be preceded by some change or changes in this relation, we have at once Ariadne's clue in our hands, which, if we follow its directions, will, in time, liberate the medical profession from the endless maze of conjectures, doubts, and difficulties, with which medicine is so much involved.

Why, it may be asked, has medicine made so little progress, compared with other arts and sciences? Is it not for want of fixed and definite principles of reasoning? Is it not evidently because there are few well understood and easily appreciable data upon which to build a solid superstructure? Can we wonder that systems, founded on gratuitous assumptions and partial limited views of nature's operations, so rapidly rise and so rapidly moulder into dust? It cannot be too frequently repeated, that no medical opinion is of the smallest worth that clashes with correctly observed phenomena, either of health or disease.

How is a correct knowledge of the anatomical nature of diseases (if I may

so speak) to be acquired? Is it not by patient and careful investigation of the symptoms of disease, compared and contrasted with an equally sedulous examination of *each and every principal organ of the body*, especially the brain, medulla spinalis, and their respective nervous cords, with great attention to the changes of relation between the vascular and nervous system throughout?

When the laws by which the motions of the heavenly bodies are well known and systematically arranged, why should we despair of medicine one day assuming that rank in the scale of sciences which its dignity and importance so imperiously demand?

In our times this is neglected, and we have abundance of speculation; but, alas! little accurate knowledge, of the real nature of disease.

If any internal part suffers pain, how can he know what the nature of the disorder is, who is ignorant of the morbid changes which the viscera undergo? or how can a cure be effected by him who knows not what part is diseased? Nor can we admit it to be cruel, as many assert it to be, to promote the welfare of mankind in general by the destruction of a few animals.

THOMAS SEEDS, M.D.

St. George's Square, Portsea.

CASE IN WHICH

A FOREIGN BODY WAS LODGED FOR NEARLY EIGHT MONTHS IN THE ANTRUM.

By J. M. ARNOTT, Surgeon.

In the month of September 1824, I was consulted by a lady who had had discharge of a yellow, occasionally somewhat fetid matter from the right nostril, for the last six or seven days, attended with pain in the cheek and corresponding side of the head. She had experienced feelings of uneasiness in the cheek during the preceding fortnight, which she attributed to having taken cold, as she believed her teeth to be sound. The matter coming from the nostril was puriform and thick, and was discharged at intervals; occasionally, more especially on awakening, she was sensible of its presence also in

the throat. No ulceration of the mucous membrane of the nostril was perceived. There was no increased redness of the right cheek; perhaps it was somewhat more tumid than the left. A small spot of caries was detected on the last grinder but one on the right side of the upper jaw: this tooth had never occasioned her pain, and striking it did not produce any; it was the only unsound tooth in the mouth. I had it extracted, and no communication existing between its socket and the antrum, three days after I drilled a hole, with a straight trocar, through the osseous partition into the latter cavity. On withdrawing the instrument its point was found smeared with purulent matter, but several hours elapsed ere this began to issue through the newly-made passage: when the first, perhaps somewhat thicker portion, had passed, it continued to flow freely.

After this the discharge from the nostril ceased, and as the patient was called into the country, it was resolved to try what effect a dependent and ready aperture for the matter might have in remedying its morbid secretion. A piece of bougie, used as a stopper, and which, for the first two days, had been introduced only during meals, was now directed to be worn, but to be taken out several times daily, to allow the evacuation of the discharge.

On the patient's return from the country in a few weeks afterwards, I was informed that the discharge had at first diminished, that it then became almost stationary, and had for some time continued nearly so; that the retention of the piece of bougie had been difficult, its presence in the mouth inconvenient, and that it had not, therefore, been constantly worn. I now determined upon introducing a silver canula, and, after repeated trials with various ones made expressly and differently formed, a tube was met with, which entering easily, remained in its place without artificial fastenings, occasioned no inconvenience, allowed a ready passage for the discharge, and could be taken out and reintroduced with facility. This was inserted on the 6th of Nov. and left to be worn in place of the bougie, its lower aperture being stopped with cork. Injections were now resorted to, at first of warm water, and subsequently of solutions of various astringent substances; these thrown

into the antrum passed freely into the nose. Solutions gradually increased in strength, of sulphate of zinc, of oxy-muriate of mercury, and of nitrate of silver; decoction of oak bark, and port wine and water, were employed, but without permanent advantage. Sometimes the discharge lessened under their use, occasionally it increased and was attended with pain, but more commonly their effect was nugatory.—Finally, after having endeavoured for more than two months to arrest the discharge by means of these local applications, they were discontinued, and the patient contented herself with washing out the antrum twice a day with water simply.

On the 7th of April last I was sent for by this lady, whom I found in a state of great alarm, from the following occurrence:—The discharge from the antrum had continued much as usual, but of late she had imagined that the silver canula was the cause of an unpleasant taste in her mouth, and mentioning this opinion to a female friend the preceding evening, this lady observed, that a piece of the pipe of the bone syringe which was used for injecting would make a very good tube, and occasion no disagreeable taste. The suggestion was inconsiderately acted upon as soon as made—a portion of the pipe of the syringe was cut off and substituted for the canula, but being unprovided, like the latter, with a rim at its lower extremity, it passed within the passage, and the alarm of the friends being excited, they made various and repeated attempts with bodkins, pointed scissors, &c. to extract it, but in vain. These attempts only served to push it further upwards, and it ultimately disappeared. Ashamed of their folly, it was only after having passed a disturbed night that the patient determined on sending for me.

On examination, I could not discern the piece of syringe pipe in the passage—it had passed fairly into the antrum. I could not, however, with the probe satisfactorily detect it there; and this, with its presumed length (three quarters of an inch), which on the moment I thought too long to allow of its turning, led me to suppose it could not have gone in; but a correct estimate being taken of the height of the antrum, the former circumstance was readily accounted for, by the limited extent of that cavity,

which it was possible to reach with the probe passed in through a small opening in the alveola; whilst the clear statement of the patient, the increased redness of the gum and cheek, and the great anxiety evinced for the extraction of the piece of pipe, dispelled any doubt of its having got within the antrum. The only mode of removing it was by trephining the walls of this cavity, but which I considered too severe an operation to have recourse to under the circumstances. The patient was informed of this, and that I should defer it until the appearance of more urgent symptoms. She was recommended merely to keep quiet, and her apprehensions of the consequences were endeavoured to be tranquillized by the assurance that the piece of bone might remain for a long time in its present situation without producing much mischief, and that it might possibly find its way out, of which, however, I acknowledge that I had little hope. The uneasiness which was felt in the cheek seemed to have been occasioned by the attempts at extraction—it subsided in a day or two, as did an increased quantity of discharge which had taken place. In the meantime, having procured an ivory tube of the same dimensions as the silver canula, it was introduced in place of the latter, and its use was unattended by the unpleasant taste attributed to the metallic one.

Contrary to what might have been expected, the abode of the piece of pipe in the antrum was not followed by any well marked effects. There was no pain, redness, or swelling of the cheek. The general character of the discharge remained the same; it was puriform and white; occasionally it increased, with slight fetor and yellow color, and some uneasiness in the part, but these changes had also occurred previously.

The patient was accustomed to remove the tube every morning and evening, to wash out the antrum, which she had now acquired the power of doing without using the syringe, by merely filling the mouth with water and forcing it to pass up through the passage into the antrum, from whence it entered the nose. On one of these occasions, in July, as she was taking a mouthful of water for this purpose, she felt something in the aperture of the passage in the gum, which she withdrew, and imagined to be a bit of old linen. I

found this to be a small piece of bougie, partially unrolled, with some of the composition off its surface; and as none had been employed since the adoption of the silver tube, this must have remained in the antrum since the preceding October. The patient had been unconscious of its entrance; and could only surmise that it had been forced up by the pressure of the bolus of food during mastication, which might readily have occurred; for, as has been already stated, she had experienced great difficulty in retaining the bougie in its place; and in the country, where she had been obliged to use some of a smaller size, the piece had frequently dropped out during meals, and been swallowed.

The descent of this body naturally encouraged the patient to hope that the piece of pipe might come down in the same way; but after the lapse of some months this hope was almost abandoned, when, on the 27th of November, as she withdrew the canula, some substance followed in the passage, which, projecting from the aperture, she drew out. This proved to be the piece of syringe pipe which had entered the antrum on the 6th of April. With the exception of being darkened in color, and the loss of its polish, this piece of bone had undergone no change; it measured almost seven-eighths of an inch in length. The accompanying drawing offers a correct representation of its form and size.

From this time the discharge from the antrum quickly subsided. At the end of ten days it had ceased; and the canula, when now kept in three days continuously, and then withdrawn, contained no morbid secretion. The employment of the canula is continued for a short time longer, that the patient may satisfy herself of the complaint being permanently cured.

It will have been noticed in the details of the above case, which I have related from its singularity, that it was difficult to retain a piece of bougie as a stopper in the opening which it was intended to close; and the patient, of her own accord, had tried cork, which was equally so. It was necessary to wear a stopper of some kind,

as the opening in the gum showed a great tendency to close; requiring, on her return from the country, that the trocar should be re-introduced to enlarge it. In resorting to a silver canula, the patient objected to this being attached by fastenings of any kind to the adjoining teeth; and an endeavour was therefore made to effect its retention by some modification of the form. But after trying several, a simple canula, of the form here represented, was
